The terms “polygenic” and “multifactorial inheritance” are sometimes used interchangeably. Nevertheless, in the exact sense, polygenic denotes to the sum total of many genes; however multifactorial also involves the interaction of environmental and genetic determinants. Some of the commonly observed multifactorial diseases include infertility, epilepsy, asthma, diabetes, high blood pressure, epilepsy, hypertension, arthritis, cancer, manic depression, and schizophrenia (Laitinen et al. 2004). Some other examples include certain developmental abnormalities such as neural tube defects (NTDs), cleft lip/palate, isolated hypodontia, and congenital heart defects (Taipale et al. 2003). A complex multifactorial trait tends to show a low heritability (proportion of total variance that is genetic) compared to single gene disorders, for example, the heritability of schizophrenia is around 81%. Similarly, the heritability of diabetes is around 40%. Also, it is observed that only 2–5% of the close relatives of diabetes also suffer from diabetes. These examples indicate that for a multifactorial disease, no single genetic factor is sufficient enough to cause the disease and it takes a complex interaction between many factors to affect the susceptibility towards the disease. This may include exposure to various environmental toxins and an individual's own genetic predisposition towards the disease.

### Characteristics of a Multifactorial Disease

A multifactorial disorder has a combination of distinctive characteristics that can be

differentiated from Mendelian or sex-limited conditions (Lobo 2008). These are as follows:

1. Multifactorial disorders are relatively common in population and fail to show a clear Mendelian pattern of inheritance.
2. The frequency of the disease display sex predilection, and it may occur more frequently in one sex than another. However, it is not sex-limited trait in which the disease is present in both, expressed in one while it remains switched off in other. Furthermore, for some diseases, the threshold of the disease is variable in both the sexes. For example, systemic stenosis disease shows a significant female preponderance than girls. Another example is congenital dislocation of the hip, which is more frequently observed in women than men.
3. Environmental factors can influence the disease risk.
4. The concordance rates in monozygotic and dizygotic twins refute Mendelian proportions.
5. The diseases are ethnically biased and appears more frequently in a specific ethnic group.

### The Threshold Model for Discontinuous (Disease) Traits

A large number of multifactorial traits such as height and intelligence show continuous variation; nevertheless, there are some disorders such as diabetes mellitus and autism that display discontinuous variation with people either being affected or not with no intermediate state. This can be explained by threshold model. However, to understand that we should first understand the term “liability.”

#### Liability

Liability is a term used to collectively explain all the genetic and environmental influences that contribute to the development of a multifactorial trait. Though it is almost impossible to estimate the liability of an individual, the liability of a group can be ascertained depending on the number of affected individuals in that group. Liability is represented as a standard distribution curve, as

most of the unaffected individuals will have some degree of liability and only a small percentage of a population will show a liability that is very low or that surpassing the threshold level.

### Threshold Model

For discontinuous traits, it is assumed that there is a liability threshold; individuals whose genetic predisposition surpasses the above will manifest the disease.

## Genomic Approaches to Decipher Multifactorial Disorders

### Traditional Approaches

Classical approaches to study multifactorial disorders involve pedigrees analysis or preparation of family trees which gives an idea of the inheritance pattern of the disease. Subsequently, the use of linkage mapping became more prevalent, and single-nucleotide polymorphism (SNP) markers along the genome were being used as reference points to investigate the DNA sequences that were co-inherited with a particular disease. These co-inherited regions were referred to be in linkage disequilibrium (LD) (Ralston 2008). However, the approach of linkage mapping had some limitations as these were typically ineffective in analyzing diseases with low heritability and those traits that are limited to small families.

### New Approaches

With the advent of omics era, novel techniques such as whole genome sequencing were used to identify disease loci. This method was utilized for comparing the genome of affected cases versus unaffected controls. The comparison was exploited to locate the potential risk causing genes or “hot spots” for a particular trait (Ralston 2008).

## Genetic Counseling in Multifactorial Disorders

For genetic counseling in multifactorial disorders, the counselor has to carefully detect the recurrence risk of the disease in the relatives of an

diseased individual. If the counselor observes that more than one children in a family is born with a multifactorial condition, it indicates either that the couple has high genetic predisposition towards the disease or they have suffered chronic environmental insult or both. Thus, the genetic counseling in multifactorial disorders is contingent upon a thorough pedigree analysis and a relevant up-to-date empirical data (Bijanazadeh 2017).

## Introduction

Animals that reproduce repeatedly across their lifespan face trade-offs between current reproductive investment and future potential reproductive opportunities (Stearns 1992). As such, the probability that a female reproduces at a given time, and the resources she then allocates to a reproductive event, is contingent upon her current condition, her prior reproductive experience, and the likelihood that she will survive to reproduce subsequently. Prior reproductive experience (parity) is particularly important in animal societies where offspring are heavily dependent on parents for nourishment and protection, with multiparous mothers tending to be more adept at raising offspring than first-time mothers (primipares). As such, variation in maternal behavior according to reproductive experience can affect the survivorship of offspring and profoundly influence their physical and social development. Since the term multiparous is largely restricted to mammalian literature, this entry draws heavily on mammals. Nonetheless, age-related increases in reproductive performance are widespread across other taxa (birds, reptiles, fish), the underlying causes of which are likely to have parallels with those operating in mammals (see Curio 1983; Forslund and Pärt 1995).

## Experienced Mothers

It is common for multiparous females in natural populations to produce larger litters and raise more resultant offspring to independence than primiparous females (Clutton-Brock 1991). As mammals are often still growing at the time of first breeding, the lower success of primiparous mothers is thought in part to reflect a trade-off between allocating energy to current reproduction versus ongoing growth and somatic maintenance. Even so, smaller females tend to produce smaller

offspring with lower survival rates independently of reproductive experience (Clutton-Brock 2016), which can make it difficult to disentangle parity effects per se from differences in female size or condition at different reproductive stages. Similarly, inexperienced mothers are more likely to occupy socially subordinate positions within animal societies, which is also associated with lower reproductive outputs. To fully understand the causes of parity-related changes in reproductive output, it is therefore necessary to quantify the behavioral, social, and physiological contributions to parental care in mothers at different stages of development.

Rather than being entirely instinctive, maternal behavior is modified by experience gained through rearing young, with the quality of care tending to improve over successive reproductive events. Notably, time spent in the proximity of offspring does not necessarily translate into improved maternal care and increased offspring survival. Instead, multiparous mothers appear to be more efficient in allocating their time to offspring, targeting their investment to periods when offspring care is most needed. For example, in feral horses in New Zealand, older mares were more protective over foals in their first 20 days of life, but were less diligent subsequently (Cameron et al. 2000). As foal mortality is highest in early life, offspring from older mares enjoy higher survivorship despite their reduced contact with foals thereafter. Support for such targeted investment is also found in wild primates such as chimpanzees (Stanton et al. 2014) and baboons (Nguyen et al. 2012). In both species, it is typical for inexperienced mothers to display closer and more prolonged contact with infants, but this does not translate into improved offspring survival. That age-related increases in reproductive success occur without increases in reproductive investment is at odds with models of residual reproductive value, which predict that females should invest more effort into each successive reproductive event as her number of potential future offspring declines. Even so, no study in a wild mammal population has accurately quantified

energy expenditure during lactation across repeated reproductive events, which would provide a stronger footing on which to compare hypotheses concerning age-related maternal investment.

Maternal investment also includes the defense of young against predators or conspecifics, the latter being particularly important in cases where females are territorial or where conspecific infanticide is commonplace. As with other behaviors, it might therefore be expected that the detection and recognition of threats to offspring, and their subsequent handling improves with reproductive experience. This was found to be the case in Belding's ground squirrels, as levels of vigilance and aggression during gestation and lactation increased with parity (Nunes 2014). Additionally, multiparous ground squirrels reacted less strongly to an introduced, caged conspecific male, more quickly recognizing the intruder as nonthreatening. Thus, the discriminatory capacity of multiparous mothers is better, allowing them to act appropriately given social circumstance.

Experience-related improvements across such a broad range of maternal behaviors imply an active role of social learning in modulating parental investment. An association between learning and maternal experience has been explored in mice and rats, where the propensity for learning, working memory, and long-term memory are all augmented in multiparous mothers compared to primiparous mothers (Pawluski et al. 2006). The strong component of learning to the expression of maternal behaviors could confer an adaptability to females, allowing parental investment to be responsive to the conditions mothers experience across their development. At a proximate level, the increased learning ability and improved competence of care in multiparous mothers is reflected in significant changes in neural biochemistry. One of various hormones implicated in such changes is oxytocin, which mediates key maternal behaviors in rats such as pup licking and pup nursing (Pedersen and Prange Jr 1988) while also being

directly involved in improving long-term spatial memory during motherhood (Tomizawa et al. 2003).

The improved targeting of maternal behaviors by experienced mothers is mirrored by improved physiological competence. In captive rats, the efficiency of energy allocation to reproduction amounts to 25% in primiparous females versus 38% in multiparous females, despite similar pup growth rates and survival from litters of standardized size (Künkele and Kenagy 1997). Supported with additional evidence such as increased milk quality and yields in primates (Hinde and Milligan 2011), it is apparent that multiparous females have greater energetic reserves available for mobilization during pregnancy and lactation than primiparous females. Hence, novice mothers often need to invest more resources per unit of reproductive output to compensate for physiological inefficiencies.

## Parity in Humans

In humans, unlike in other animal societies, offspring born to multiparous females are frequently considered to be at a disadvantage. Ideas concerning “firstborn advantage” can be traced to Francis Galton, who noted a preponderance of firstborn sons in eminent positions in 1874 (Galton 1874). More recent treatments similarly support an association between birth order and intelligence and importantly, provide good evidence that this association arises through social rank effects rather than through gestational effects; later-born Dutch conscripts that lose an elder sibling as a child attain an adult IQ score comparable to men of higher birth order (Kristensen and Bjerkedal 2007). Firstborn advantage in contemporary human populations is reflected in various other metrics, such as increased nourishment (Ballweg and Pagtolun-An 2002), better schooling (Black et al. 2005), and improved healthcare (Kaplan et al. 1992). Consequently, although human mothers encounter problems of physiological inefficiency when

breeding for the first time as in other mammal species (offspring born to multiparous mothers are heavier at birth (Kaplan et al. 1992)), this initial deficit is compensated for by reduced sibling competition and increased parental attention. Theoretically, firstborn children are favored even if parental resources are distributed equally among children at any given time (Hertwig et al. 2002).

Yet, despite many studies highlighting the reduced performance of offspring born to multiparous females, in various human societies the pattern is absent or reversed. For example, in the hunter-gatherer !Kung communities of Southern Africa Draper and Hames (2000) found a positive relationship between birth order and reproductive success. Among population differences in birth order effects are regularly attributed to differential patterns of land and wealth inheritance, patterns that can be understood under Darwinian considerations of the resource-holding and reproductive potential of individuals (Hrdy and Judge 1993). In this regard, it is easy to see how the historically widespread practice of primogeniture, the right of firstborns to parental wealth, would tend to disfavor offspring born to multiparous mothers. In contrast, the !Kung lack divisible material wealth, meaning that lastborn individuals in !Kung families might benefit from a larger number of siblings, and thus kin-directed assistance, across their reproductive lifespan (Draper and Hames 2000). Clearly, both cultural and biological factors must be taken account of when thinking about multiparity in humans (Hrdy and Judge 1993; Draper and Adams 2000; Myrskylä et al. 2013; Savage et al. 2013; Derraik et al. 2016; Rohrer et al. 2015).

### Definition

Muscle tissue is a specialized structure in the body of animals that acts by contracting myosin and actin, creating movement when stimulated by nervous tissue, specialized conducting fibers, or hormones.

### Introduction

Muscle tissue is found throughout the body and allows for movement by contraction. There are three different types of muscle tissue: skeletal muscle, cardiac muscle, and smooth muscle. The name given to muscle tissue is usually related to its location or characteristic appearance microscopically. When muscle tissue contracts or becomes shorter, the body or organ in the body move in a given direction. While each of these muscle types shares similar functions, they individually possess unique characteristics. “Locomotion, movement through the environment, is the behavior that most dictates the morphology and physiology of animals” (Dickinson et al. 2000, p. 100).

### Muscle Contraction

For the purpose of understanding general muscle contraction, it is important to know that muscle fibers are composed of smaller units that are grouped in a longitudinal fashion where portions interlock with one another at a microscopic level. Two proteins make up the contractile elements of striated muscle: the thick filamentous fibrous

protein cluster named myosin and the thinner filamentous protein named actin. Striated muscle includes cardiac and skeletal muscle and is distinguished as striated because the myosin and actin proteins are organized in a striped fashion. Smooth muscle, as the name suggests, organizes its contractile proteins differently and does not produce the striated appearance.

The interaction of myosin and actin filaments is regulated by other proteins (aptly called regulatory proteins). These proteins determine when actin-binding sites are available for myosin binding. Myosin-binding site regulatory proteins (troponin & tropomyosin) are found along the actin filaments and cover the actin-binding sites, preventing them from binding to myosin. In turn, these regulatory proteins are controlled by calcium ions. Contraction occurs when the myosin and actin bind together to produce movement.

When nerves within the muscle receive electrical signals that travel through muscle cells, calcium is released. As calcium ions increase around the contractile filaments, they bind to a portion of troponin, one of the regulatory proteins, allowing actin to bind with myosin causing muscle contraction. Muscle contraction typically ends when electrical signals stop being sent and calcium is resorbed.

Adenosine triphosphate (ATP) is the chemical molecule that powers muscle contraction. At the beginning of contraction, the myosin head is bound to actin molecules and Adenosine triphosphate (ATP) is absent. In order for release to occur, ATP must bind to the myosin head, which in turn causes a change in shape of the actin-binding site. This conformational change loosens the bond and causes the myosin head to release from the thin actin filament. The ATP-binding sites undergo further conformational shape shifting, causing the myosin head to bend. The myosin head movement is caused by the breakdown of ATP into Adenosine diphosphate (ADP) and inorganic phosphate; both of these products remain bound to the myosin head. This causes the myosin head to linearly displace relative to the thin filament. Once the myosin heads weakly bind to its new sites, inorganic phosphate is released, which has two effects. First, the bond increases with strength

and, second, the myosin head generates a force as it returns to its original unbent state forcing the thin filament to move along the thick filament. During this step, ADP is lost from the myosin head. To fully understand this concept, imagine the actin molecules as marbles that run along the length of a rope – the rope being the thin filament, which allows a numerous amount of binding sites for the myosin head to continually progress the thin filament forward to further the contracture.

A practical application of the above text helps us understand the phenomenon of muscle rigidity or muscular contraction experienced after death, known as rigor mortis. When an animal dies, ATP production is terminated, and thus no energy is produced. Since it requires more ATP for muscle relaxation than contraction, this explains why rigor mortis occurs following death.

### Three Main Types of Muscle Tissue

#### Skeletal Muscle

Skeletal muscle is attached to bone (or the skeleton) and is responsible for the majority of body movements, its position, and posture. These muscles perform functions such as walking, swallowing, and urination. “Skeletal muscles also protect internal organs by acting as an external barrier or shield to external trauma and by surrounding the weight of the organs” (Kaufmann et al. 2018, 10.1). Skeletal muscles are under voluntary or conscious control in contrast to smooth muscles, which are under involuntary or unconscious control.

“Each skeletal muscle has three layers of connective tissue that enclose it, provide structure to the muscle, and compartmentalize the muscle fibers within the muscle” (Kaufmann et al. 2018, 10.1). An individual muscle is surrounded by a thick connective tissue termed the *epimysium*, “which allows a muscle to contract and move powerfully while maintaining its structural integrity. The epimysium also separates muscle from other tissues and organs in the area, allowing the muscle to move independently” (Kaufmann et al. 2018, 10.1). Moving within the epimysium, there are individual bundles of muscle fibers termed

fascicles. These individual bundles are organized within another connective tissue termed the *perimysium*. “This fascicular organization is common in muscles of the limbs; it allows the nervous system to trigger a specific movement of a muscle by activating a subset of muscle fibers within a fascicle of the muscle” (Kaufmann et al. 2018, 10.1). Lastly, each fiber has its respective connective tissue covering termed the *endomysium*.

At each end of the skeletal muscle, the connective tissues merge to form connective tissue tendons, which is how each muscle is attached to a particular place. Tendons are usually understood to connect muscles to bone; specifically, the tendon fuses with the periosteum covering of the bone. The periosteum is described as a vascularized connective tissue that surrounds bones, except at joints. As muscle fibers contract, tension is distributed through the connective layers, through the tendon, and finally to the periosteum, which pulls on the bone allowing movement of the skeleton (Kaufmann et al. 2018). Tendons hold such impressive tensile strength that when exposed to extreme forces, a tear in a portion of muscle or a break of bone where the tendon attaches is more likely to occur (Dyce et al. 2010).

Muscles receive blood supply and innervation from nearby arteries and nerves, which travel through the various layers of connective tissue. They branch into even smaller extensions as they travel inwards, toward the endomysium and underlying fibers. An important distinction skeletal muscle has from other muscle tissues is its innervation by the somatic nervous system (SNS). The SNS is under conscious voluntary control and allows movement from skeletal muscles to be controlled consciously. “Unlike cardiac and smooth muscle, the only way to functionally contract a skeletal muscle is through signaling from the nervous system” (Kaufmann et al. 2018, 10.1).

Skeletal muscle can vary in color and appearance which is partly determined by the amount of myoglobin within the fibers. “Myoglobin is an oxygen-binding protein that closely resembles hemoglobin found in erythrocytes (red blood cells) and occurs in varying amounts in muscle

fibers. It provides a ready source of oxygen for muscle metabolism” (Ross and Pawlina 2011, p. 313). Most skeletal muscle is composed of three fiber types, of which the proportions vary. Of these three, type I fibers (slow oxidative fibers) are colored red and are small in size. They contain many mitochondria and high levels of myoglobin concentration; explaining why type I fibers exhibit impressive endurance and take longer to fatigue. “Importantly, type I fibers are the primary fibers of the long muscles of the back in humans, explaining how maintaining an erect posture is possible for long periods of time” (Ross and Pawlina 2011, p. 313). Type IIa (fast oxidative glycolytic fibers) fibers also contain high levels of myoglobin and mitochondria; however, they contain high levels of glycogen and therefore are capable of anaerobic glycolysis. These components allow type IIa fibers to be termed fast-twitch fatigue-resistant motor units. Type IIb (fast glycolytic fibers) are larger fibers, which are also red in color. They contain less myoglobin and mitochondria than the previously discussed fibers. They contain high levels of anaerobic enzymes in addition to a large amount of glycogen. While their ability to utilize energy is the fastest of the fibers, they also fatigue rapidly due to lactic acid production. This explains their adaptation for rapid contraction and accurate movements, such as dexterous movements like playing the piano. An interesting example of the importance of the contribution of these fibers can be observed in the instinctive rapid swim movement of shrimp. “Forty percent of the body mass of a shrimp is devoted to the large, tasty abdominal muscles that produce a powerful tail flick during rare, but critical, escape behaviors. During escape, rapid acceleration, rather than energy minimization, is the relevant aspect of performance” (Dickinson et al. 2000, p. 102).

### Cardiac Muscle

Cardiac muscle makes up a majority of the heart. As discussed earlier, cardiac and skeletal muscle have the same organization and types of contractile filaments. A difference cardiac muscle has when compared to skeletal muscle is its intercalated disks that connect individual cardiac muscle

cells. These intercalated disks serve as an important component of the synchronized contraction that cardiac muscle exhibits. Gap junctions are found within the intercalated disks and “provide ionic continuity between adjacent cardiac muscle cells, thus allowing informational macromolecules to pass from cell to cell” (Ross and Pawlina 2011, p. 330), ultimately enabling cardiac muscle fibers to behave as one, while retaining cell-self. The heart beat exhibits continuous contraction by unique cardiac muscle cells and conducting fibers known as Purkinje fibers.

Sympathetic and parasympathetic nerves communicate with these parts of the heart by stimulating the heart to increase, or decrease in rate, conduction, and contractility. The sympathetic nervous system, most commonly referred to as “fight or flight,” typically happens in situations of panic. The parasympathetic system is referred to as “rest or digest.” An example of sympathetic drive would be a gazelle running from a cheetah. The gazelle’s sympathetic nervous system would take over the parasympathetic, increasing cardiac contractions. This would allow more blood to flow through vessels, resulting in more oxygen delivery throughout the body, giving the gazelle a chance to endure the race for life.

Trauma to an area of the heart resulting in injury can cause that portion of cardiac muscle tissue to die and eventually be permanently replaced with fibrous connective tissue. Fibrous connective tissue, commonly termed scar tissue, is responsible for repairing injuries to many tissues of the body. Unfortunately, when a portion of the heart dies or becomes scar tissue, cardiac function is lost at that site. This type of cardiac injury is commonly referred to as myocardial infarction or heart attack.

### Smooth Muscle

Smooth muscle is termed so because of how its contractile proteins are organized in appearance at the microscopic level. They surround blood vessels and internal organs, such as the digestive tract. Smooth muscle is under involuntary control and can be stimulated by hormones and conduction from the autonomic nervous system (Kaufmann et al. 2018). The autonomic nervous

system can be further broken down into the sympathetic and parasympathetic nervous system. As described earlier, the parasympathetic nervous system is critical for digestion. Parasympathetic stimulation encourages oxygen delivery and other useful materials to support the energy required for digestion, such as the propulsive movements by smooth muscle directing ingested material through the intestinal tract. If sympathetic stimulation were to occur, oxygen delivery would be directed toward other areas of the body in need. Smooth muscles are able to operate with coordination because of the gap junctions found between its cells. “Single-unit smooth muscle produces slow, steady contractions that allow substances, such as food in the digestive tract, to move through the body” (Kaufmann et al. 2018, 10.7).

## Conclusion

Muscle tissue is made up of muscle cells grouped together in the body of animals. The proteins that make up muscles is comprised of actin and myosin. Contraction or movement by muscles occurs when the proteins slide past each other forming tension that changes the shape of muscle cells and can create significant or subtle force for motility. Contraction requires energy or ATP to occur. Muscle tissues are either voluntary (striated) or nonvoluntary (smooth) and are divided into skeletal, cardiac, and smooth. Muscle tissue is responsible for locomotion, posture, shape, heartbeat, and other organ movement such as intestinal contractility to help pass food throughout the gastrointestinal tract.

## Introduction

Mustelids are a large family, with 60 species found in Eurasia, Africa, Asia, North and South America (Koepfli et al. 2008). As shown in Table 1, the family contains eight subfamilies, with many fascinating species like the European badger (*Meles meles*), the sea otter (*Enhydra lutris*), and the wolverine (*Gulo gulo*), to name but a few.

Communication in mustelids is closely related and dependent on the species' respective social system and habitat (Buesching and Stankowich 2017). The social and spatial organization of mustelids is highly variable between species, but there may be also variation in different populations of the same species (Kruuk 2006; Newman et al. 2011). Divergence of a pure solitary lifestyle is induced by environmental

**Mustelid Communication, Table 1** Subfamilies and number of genera and species in the family of mustelids. Each genus is shown with one exemplary species. The number of all genera and species is given in the

subheadings for each subfamily (genera/species). All subfamilies are depicted with one representative species. Taxonomy following Koepfli et al. 2008

factors such as habitat, geographical distribution, ecomorphology, resource dispersion, or season (Johnson et al. 2000). The socio-spatial organization of mustelids is based on the “classical” system of one male territory encompassing distinct female territories. Several variations of and exceptions from this basic pattern exist as well (Kruuk 2006).

As knowledge on mustelids accumulates, several species which formerly have been described as purely solitary turn out to be more social, or have at least a much more flexible social lifestyle (e.g., Newman et al. 2011).

Each communication channel has its advantages and disadvantages. One may be more useful than the others, depending on when, where, and which information needs to be transmitted. Compared to acoustic signals, chemical markings

persist for an elongated time, thereby allowing conspecifics or co-occurring species to gather information even in the physical absence of the sender. In a habitat where olfactory cues cannot be deposited, acoustic communication may be favored (Fig. 1). This is especially true for the subfamily of otters. With the exception of sea otters (see below), they show a semiaquatic lifestyle and only use scent-marking on land (Kruuk 2006).

### Olfactory Communication

Olfactory communication has a multipurpose function. It is regarded as the most important communication channel for mustelids, probably because all mustelids are territorial and scent-

**Mustelid Communication,**

**Fig. 1** Mustelid communication in three sensory channels. Olfactory communication: two examples of scent-marking postures; acoustic communication: spectrograms of vocalizations showing frequency over time; visual communication: throat patterns likely used for visual (Picture credits **a**, **c**, **d**, **f**, and **g** by Christina Mumm, **b** and **j** by Pia Weidenmüller (written license), **e** by Hannah Heitherr (written license), **h** by user 422737 on pixabay (CC0 license), **i** by user Ellis Lawrence on flickr (CC BY-SA 2.0 license). mark their territories to announce ownership. It further allows mustelids to signal information on reproductive state, as well as information on identity and food resources. To exchange more detailed information, the animals may vary frequency and location of markings.

Territorial scent-marking can be done by the deposition of feces, urine, or a combination of both (i.e., excremental marking, see Fig. 1a), as

well as through gland secretion (i.e., secretional marking). Secretion may be produced in anal, ventral, foot, or subcaudal glands and applied by body rubbing, anal drag, or scratching (see Fig. 1b). Gland secretions can also be used to mark conspecifics. In some species, territorial scent-marking is enhanced by visually marking the surroundings, e.g., by scratching the ground or trees (e.g., Hutchings and White 2000;

Leuchtenberger and Mourão 2009). Otter spraints consist of feces, anal gland secretion, and often of a third compound, the “jelly.” Not much is known about this slimy substance, the only available information is that it “is secreted somewhere in the intestine itself” (Kruuk 2006). Chemical composition varies among feces, urine, and gland secretion, thereby allowing for the transmission of differential information (Clapperton 1989).

Deposition of scent is not random in time and space (Kilshaw et al. 2009). For scent-marking, the animals select prominent places, on stones, under bridges, or on other landmarks, which are frequently revisited (Hutchings and White 2000). Otters may even choose marking places which are relatively far and visit them repeatedly (Kruuk 2006). Furthermore, European badgers do not only carefully select marking places, but also the positioning of scent inside each place (Stewart et al. 2002). As badger territories contain more than one latrine site, the animals systematically revisit several places to refresh their scent marks (Kilshaw et al. 2009).

Social species like European badgers and giant otters (*Pteronura brasiliensis*) make use of communal latrines – enlarged areas for the deposition of excremental and secretional marks from all group members. Giant otters regularly clear off the vegetation at communal latrines. Otters in general show an elaborate marking behavior because the deposition of excremental and secretional marks can be accompanied by a scent-marking “dance.” Giant otters, as well as spotted-necked otters (*Lutra maculicollis*), and North American river otters (*Lontra canadensis*) show dance-like stepping postures, accompanied by intense sniffing. Giant otters use their forepaws for dancing, while spotted-necked otters and North American river otters use their hind legs. Some species may also smear feces from different individuals with their paws or tail to create a typical group odor (e.g., Buesching et al. 2016; Leuchtenberger and Mourão 2009; Rostain et al. 2004).

In several mustelids scent-marking frequency shows seasonal changes, mainly with a peak in the mating season. Mustelids scent-mark within their territory (“hinterland latrines”) or at territorial

borders (“boundary latrines”). Both types have different functions, which are best described in badgers. The use of different latrine sites depends on population density and season. In high-density populations, European badgers form social groups, whereas in low-density populations, groups mainly consist of a pair and their offspring. Larger groups have more latrines inside their home range, but space is limited in high-density populations, so that these groups usually occupy smaller areas. They invest mainly in boundary latrines; however, their function in territorial defense is not fully understood (Buesching et al. 2016). Nevertheless, European badgers can discriminate between feces from neighboring and alien groups and react more aggressively towards the scent of alien groups. Smaller badger groups in low-density populations may use larger areas, but their ability of marking is limited by the number of individuals. Therefore, small groups may neglect boundary latrines and the use of hinterland latrines peaks during mating time. Latrine use is even abandoned seasonally, when home range size is enlarged. This shows a trade-off between group size and the area a group is able to defend, either in terms of limited space or in terms of limited number of individuals marking the latrines (Buesching et al. 2016). Population density also affects the main information provided at latrines: they likely function to signal territoriality in high-density populations, but reproductive state and other individual information in low-density populations (Zhou et al. 2015). In low-density populations of Japanese badgers (*Meles anakuma*), information provided at both latrine types eases information exchange about presence, identity, and hormonal state of females, and Japanese badgers visit boundary latrines most often during mating season (Kaneko et al. 2009). Hog badgers (*Arctonyx collaris*), which are described to be solitary, use latrines for a different reason: they signal the location of food resources (Zhou et al. 2015). This behavior is also found in coastal Eurasian otters (*Lutra lutra*), which mark food patches and freshwater pools to signal their use of these resources (Trowbridge 1983). Scent-marks allow them to inform conspecifics that the resource is already depleted, and avoid direct

competition and confrontation. Besides its importance for signaling territoriality and reproductive state, excremental markings may also aid in spatial orientation. For instance, Eurasian otters mark locations where their trails change direction (Trowbridge 1983).

The only mustelid in which excremental marking is absent is the sea otter. This exception is due to its exclusive aquatic lifestyle, differing from all other otters, which have a semi-aquatic lifestyle. Instead of scent marking, male sea otters defend their marine territories during the mating period by patrol swimming, splashing, and direct chases of rivals (Kruuk 2006).

Secretional marking is also important in territoriality, spatial organization, and individual information exchange. Dominant males of European badger groups intensify secretional marking of females during mating season (Kruuk et al. 1984). Individually distinct odor cues are found in several mustelids. Ferrets (*Mustela putorius furo*) do not only distinguish the deposition time of conspecific odor, but also discriminate between different individuals because the composition of volatiles is individually distinct. The combination of this information enables ferrets (and likely all other mustelids) to learn movement patterns of conspecifics, adjust their activities accordingly, and thereby avoid direct aggressive encounters.

Even though mustelids may encode individual identity in all available signal modalities, most studies focus on olfactory communication. Experiments on olfactory discrimination or recognition in mustelids are restricted to a few species, and older studies often tested only one focal animal, thereby providing descriptive indications rather than reliable statistical data for further comparisons.

Volatile compounds produced by mustelids differ between species, and show sufficient variation to encode sex, age, and individual identity (Brinck et al. 1983). Identity cues can either be encoded by presence or absence of certain compounds and/or through the amount and composition of the chemical compounds. For instance, gland secretions of Siberian weasels (*Mustela sibirica*) and the urine of ferrets contain sex-specific chemical compounds, while steppe

polecat (*Mustela eversmanni*) secretions encode sex in the relative abundance of different compounds (Zhang et al. 2002; Zhang et al. 2005).

Group or family odors can be created by secretional marking of conspecifics; cubs, mates, or other group members are normally labeled by body rubbing (Duplaix 1980). Group odors can be combined with individual distinct odors as well. For instance, European badgers use the scent from their subcaudal gland to create a group odor and to share individual information, especially about their reproductive state (Buesching et al. 2003). They distribute their group odor through mutually marking each other, but deposit their individually distinct odor by sequential allo-marking, i.e., one badger rubbing its scent onto the fur of other group members (Buesching et al. 2003).

The function of scent cues may also be influenced by composition of social groups. North American river otters, for instance, show a flexible social organization. When females rear their young, they may build family groups, sometimes with elder helpers, or stay solitary, while males may form temporary groups of up to 30 individuals (Larivière and Walton 1998). Group-living females use scent cues for territorial maintenance and solitary individuals use them for avoiding direct encounters with conspecifics (Ben-David et al. 2005). Whereas in male groups, scent cues help to maintain a dominance hierarchy (Rostain et al. 2004).

In areas where different mustelid species co-occur, interspecies competition seems to be low due to different habitat and dietary preferences or foraging strategies (Hussain et al. 2011). Nevertheless, interspecific territoriality and social dominance are most likely communicated via olfactory cues.

Several mustelid species, e.g., the striped polecat (*Ictonyx striatus*) and the African striped weasel (*Poecilogale albinucha*), can produce chemical defensive sprays (Apps et al. 2015; Larivière 2001), comparable but not as strong as those known from skunks (*Mephitidae*). Other mustelids, such as the American mink and the honey badger (*Mellivora capensis*), do not directly spray, but also produce deterrent secretion when threatened (Brinck et al. 1978; Vanderhaar

and Hwang 2003). The respective volatile compounds are produced in anal glands, and are foul and strongly smelling (Apps et al. 2015; Larivière 2001).

Currently, no information on the mustelids' sense of smell is available but it is conceivable that their olfactory perception is highly sensitive, given the importance of odor cues for social communication.

## Acoustic Communication

Many mustelids are extremely vocal and often engage in screaming, hissing, chuckling, squeaking, and squealing. Mustelids may signal identity cues, intention, stay in contact or beg for food via the acoustic channel. Some vocalizations also play a role in territorial defense. Nevertheless, peer-reviewed publications of the vocal repertoire exist for only 12 species and anecdotal descriptions are available for only 14 more (for an example of European pine marten calls see Fig. 1d). The acoustic communication of the remaining 34 species has not been studied so far (Table 2). There are no publications on acoustic communication in Helictidinae, and Taxidiinae. Most descriptions are found for the subfamily of otters. Outstanding in terms of vocal complexity are two representatives of the otters: the Asian small-clawed otter (*Aonyx cinerea*) and the giant otter (*Pteronura brasiliensis*).

To date, giant otters are the best studied mustelid concerning acoustic communication. Several authors described the vocal repertoire to consist of 15–19 distinct vocalizations (see some examples in Fig. 1c). This elaborate repertoire is further enlarged by gradations between calls. Like in many other otter species, such as sea otters, or Asian small-clawed otters, several giant otter vocalizations show enough variation in acoustic cues to provide individual differences and the potential for vocal discrimination and recognition (Leuchtenberger et al. 2016; Mumm and Knörnschild 2014). Giant otters use contact calls and hums for group cohesion and can discriminate between different individuals based on these

vocalizations alone (Mumm et al. 2014). Correspondingly, Asian small-clawed otters derive sufficient information from their contact calls to distinguish their mates from unknown individuals (Lemasson et al. 2013). Group screaming (a territorial vocalization) and snorts (a type of alarm call) provide acoustic information on group identity, thereby aiding giant otters in territorial defense. Moreover, acoustic parameters of snorts encode the sex of the calling individual, an aspect which is not prominently reflected in the physical appearance (Leuchtenberger et al. 2016; Mumm and Knörnschild 2017).

Some studies describe vocalizations of cubs. Apparently, innate precursors of the adult vocal repertoire are found in all species studied to date. Giant otter cubs emit adult-like vocalizations from birth on and combine them in long babbling bouts, presumably to practice. Some cub calls are age-specific and disappear during development (Mumm and Knörnschild 2014). American mink cubs are also vocally active from birth on. However, studies on hearing development in ferrets and mink cubs could show that hearing starts not earlier than around 30 days of age (Brandt et al. 2013; Moore and Hine 1992).

Hearing ranges and thresholds are known for six mustelid species. The hearing ranges of semi-aquatic otters and minks are largely comparable, while ferrets and stoats have a broader range. Best hearing lies between 1 kHz and 16 kHz (compare Brandt et al. 2013; Ghoul and Reichmuth 2012; Heffner and Heffner 1987). Overall, the hearing capacity of mustelids is comparable to other carnivores (Ghoul and Reichmuth 2012; Heffner and Heffner 1985). In tests for hearing and sound localization accuracy, least weasels performed better than their prey species (rodents), which underlines the selective pressure on carnivores for good sound detection abilities in order to localize their prey (Heffner and Heffner 1987).

## Visual Communication

Fur coloration and body postures are apparent in several mustelid species, but vision is poorly

studied, with only seven publications on five species (three otter species, European polecat, and ferret). Only one, but a very interesting study deals with visual cues in mustelids (Newman et al. 2005).

The otter eye is equivalent to that of other terrestrial mammals. Same visual acuity in air and underwater is achieved by an accommodation process which offsets loss of corneal refractive power underwater. The retinal resolution angle is about 14' in Asian small-clawed otters (Balliet and Schustermann 1971), and 7' in sea otters (Mass and Supin 2000), which is close to the angle of 5' in pinnipeds. European polecats and ferrets have a resolving angle of 16' (Neumann and Schmidt 1959). The amplitude of accommodation in sea otters is 60D and thereby comparable to that of humans (58D) (Murphy et al. 1990). Thus, we think that the often proposed poor visual abilities of mustelids can no longer be supported.

Fur coloration in mustelids reaches from inconspicuous unicolor (as in the Lutrinae), over contrasting black-and-white (as in the Galictinae) to a vivid coloration in the marbled polecat or the yellow-throated marten (*Martes flavigula*). Several species have facial masks, e.g., grisons and badgers, or individually distinct throat markings, e.g., giant otters and European pine martens (Fig. 1e–j) (Newman et al. 2005). Facial masks and throat markings may have different functions: facial masks are most likely a warning signal since they are found in species which produce defensive sprays and anal gland secretion in threatening situations (Newman et al. 2005). Throat markings, on the other hand, probably play a role in individual communication. Many mustelids stand on their hind legs when monitoring their surroundings, and giant otters periscope out of the water when detecting unknown or threatening objects (Duplaix 1980). This behavior gives conspecifics ample opportunity to see the throat pattern. Nevertheless, it remains to be tested whether mustelids make use of throat markings for visual or multimodal individual recognition.

## Multimodal Communication

Not much is known about the information mustelids can derive by combining signals in different modalities. Asian small-clawed otters are the only mustelid species for which multimodal discrimination of conspecifics has been tested experimentally (Lemasson et al. 2013). Females are able to discriminate their male partners from unfamiliar males based on scent and vocalizations. They did not react to life-size photographs, which may either show the minor importance of visual cues or their inability of visual discrimination.

## Conclusion

Mustelids use different modalities for communication. Like many mammals, they exchange information about territorial ownership, hormonal state, and individual cues like group membership, or sex and age. The mostly solitary lifestyle in this family may account for the importance of signals which do not require direct contact for communication. This is achieved via olfactory markings. Nevertheless, visual communication in terms of fur coloration and body postures also plays a role in mustelid communication. The more social the species, the more important becomes the acoustic channel, allowing group members a fast and direct information exchange.

Despite the growing literature on social communication in mustelids, there is an obvious lack of knowledge about perception and processing of olfactory, acoustic, and visual cues. There are many limitations hampering experimental approaches for the study of communication and cognition in mustelids: several species are elusive, solitary, and/or protected; basic data on behavior and ecology is lacking; captive holdings have only a few or one individual; and animal training strongly depends on cooperation and attention span of focal animals. Furthermore, experimental design needs to be sophisticated, and properly adjusted to the respective species

(compare Mumm et al. 2014; Trowbridge 1983). Nevertheless, mustelids are a highly promising family for future studies, especially regarding multimodal communication and self-recognition. Moreover, the variety of social organization in mustelids is well suited to investigate the positive feedback loop between social and communicative complexity.

## Mustelidae Cognition

Chris Newman and Christina D. Buesching  
Wildlife Conservation Research Unit, Department  
of Zoology, University of Oxford, The Recanati-  
Kaplan Centre, Oxford, UK

### Introduction

Due to their apparent intelligence and adaptability, mustelids typically thrive if introduced into new ranges and increasingly they live among us even in urbanized areas (e.g., stone martens (*Martes foina*): Hisano et al. 2016). Yet, despite our general acquaintance with some members of this family, many aspects of their behavior, and particularly their cognitive abilities, remain more mysterious than those of their canid and felid cousins. This is likely due to their smaller size and more nocturnal lifestyle as well as being less amenable to being domesticated (with the singular exception of the domesticated ferret *Mustela putorius furo*). In this chapter we explore why this should be, identifying that despite being unified as “long, thin, and stinky,” they exhibit a diversity of cognitive traits linked to their form and function, powers of perception, and communication, resulting in disparate extents of social behavior and cognitive abilities.

### The Constraints of Form, Function, and Physiology on Cognition and Behavior

Mustelids have short, tough limbs ending in five-toed paws attached by a highly flexible wrist/ankle, and they exhibit greater paw variation than any other carnivore family (Kitchener et al. 2017). Iwaniuk et al. (1999) caution that – in fissioned carnivores – brain size is not correlated with forelimb dexterity, and that disparate ecological and phylogenetic factors act in concert to promote or constrain neural development and behavior in different species. Nevertheless, having free “hands” able to manipulate objects opens

up a range of ecological possibilities, ensuing specific intellectual and brain-developmental characteristics. Indeed, sea otters are one of the few nonprimate mammals known to use tools on a regular basis (Fuji et al. 2014), employing a specially chosen rock held in their forepaws to break open shellfish and clams collected under water. Similarly, in captivity, Asian small-clawed otters (*Aonyx cinerea* syn. *Amblonyx cinereus*) appear capable of understanding the application of specific tool use ahead of feeding bouts in behavioral enrichment trials, pulling hooks to activate levers to release fish (Frick et al. 2016). Other mustelids, such as martens and tayra use their strong dexterous paws to climb, where the balance and three-dimensional spatial awareness required to move along thin and bendy branches resulted in extremely rapid information processing (Taylor 1989). Crucially, however, because these typical stubby limbs preclude figuratively “running with the pack,” and thus predatory mustelids tend to be solitary, limiting the opportunity for direct social behaviors (and related social intelligence) to manifest (Table 1).

### Sensory Perception, Recognition, and Communication

Cognition is highly dependent on sensory perception (Pecher and Zwaan 2005) and is intimately linked to the evolution of life-history strategies. Because many mustelids are nocturnal, or very short-legged, their range of vision is generally limited. Instead they tend to rely on their hearing and especially on olfaction for orientation, hunting, and communication (Buesching and Stankowich 2017). The receiver’s “psychological landscape,” which determines detectability, discriminability, and memorability of the cue after it reaches his sensory organs (Guilford and Dawkins 1991) is particularly important in our context of cognition, as it allows, for instance, conspecifics to recognize each other’s vocalizations or scent marks even after periodic absence (e.g., Buesching and Stankowich 2017).

**Mustelidae Cognition, Table 1** The relationship of cognitive abilities with diet, habitat use, communication and social behaviors in Mustelids

| Genus (species or broad group)                                              | Habitat use/special cognitive abilities                                                                                                        | Social system                                                                               | Diet/foraging strategy                                                                                                                                                                      | Communication                                                                                                                                                                                                            | Cooperative/key behaviors                                                                                                                                                          |
|-----------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Mustela, Poecilogale, Vormela, Ictonyx, and Lyncodon (weasels and polecats) | Cursorial/subnivean weasels; fossorial polecats/ferrets (cathemeral, linked to prey availability)                                              | Solitary                                                                                    | Carnivorous/predatory                                                                                                                                                                       | Predominantly via scent, including feces, urine, and anal and dermal gland secretions, involving body dragging and rubbing. Vocalizes only in aggression/distress                                                        | None. No mutual interactions outside of mating, maternal care, and territorial defense                                                                                             |
| Martes and Pekania (martens)                                                | Climbing (scansoriality) and subnivean predation, with adaptations to deep snow. Activity patterns relate to prey availability and temperature | Solitary – some species will congregate at rich feeding sites (fruit trees/carcasses)       | Omnivorous/opportunistic generalists. Can assess need for protein in diet (vs. fruit) during cold conditions. Fisher map porcupine dens/trees                                               | Predominantly via scent, including feces, urine, and anal and dermal gland secretions, involving body dragging and rubbing. Vocalizes only in aggression/distress                                                        | None. No mutual interactions outside of mating, maternal care, and territorial defense. Will congregate around rich food sources (carcass scavenging, fruiting trees) <sup>a</sup> |
| Meles (European and Asian badgers)                                          | Fossoriality (nocturnal)                                                                                                                       | Continuum from solitary to group living with increasing population densities – forage alone | Omnivorous/opportunistic generalists (some populations specializing on earthworms – with availability mapped to weather and microclimate). Can map out rabbit nests and grub-rich dead wood | Predominantly via olfaction, including specialized subcaudal gland secretion used to mark objects and conspecifics. Feces (anal gland) and urine used in territory marking. A range of intraspecific vocalizations noted | In social-group living populations, allo-grooming, allo-marking, some suggestion of occasional allo-parental care. Purely reciprocal                                               |
| Arctonyx (hog badgers)                                                      | Fossorial (nocturnal)                                                                                                                          | Solitary                                                                                    | Omnivorous/opportunistic generalists                                                                                                                                                        | Predominantly via olfaction, including specialized subcaudal gland secretion used to mark objects. Feces (anal gland) and urine used in territory marking. A range of intraspecific vocalizations noted                  | None. No mutual interactions outside of mating, maternal care of offspring                                                                                                         |

## Eyes and Vision/Ophthmoception

Most mustelids are nocturnal, but many *Mustela* species and lutrines are cathemeral (i.e., no bias toward diurnal vs. nocturnal activity). While more diurnal species, such as various *Martes* species, have greater acuity enabling them to resolve fine spatial detail through reduced retinal summation

(i.e., the ratio of photoreceptors to ganglion cells: Kitchener et al. 2017), nocturnal species have relatively larger and more curved eyeballs with high rod/cone ratios, making the most of available light to summate retinal images, but at the cost of acuity. Certainly the nocturnal European badgers (*Meles meles*) react to the unfamiliar silhouettes of

human observers, even if sitting perfectly still, whereas the cathemeral American mink and ferrets can be taught to discriminate successfully between different objects with an ability rivaling primates (Doty et al. 1967). Semi-aquatic lutrines on the other hand can see in both air and under water and can learn to discriminate submerged targets for food rewards equally in both environments (Balliet and Schusterman 1971). Because many lutrines, *Mustela* species, and martens have evolved distinct throat patches that are highly visible when the animal is scanning its environment – a typical response to contact calls from conspecifics – and which provide a useful aid for human observers to distinguish individuals (e.g., Sirén et al. 2016), Buesching and Stankowich (2017) suggested that these throat patches may also aid in individual recognition among conspecifics.

### Ears: Hearing/Audioreception

Interestingly, mustelid sound localization acuity is typically lower than that of larger carnivores. Heffner and Heffner (1987) propose that this acuity may be limited by their interaural distance, thus shifting the cognitive bias toward other senses. Yet, many mustelids use vocalizations as interspecific communication signals, although this is typically limited to aggressive or maternal-offspring calls in solitary species, with more complex repertoires evident in those few group-living species. For example, Asian small-clawed otters can recognize vocalizations from individual conspecifics in experimental playback experiments (Lemasson et al. 2014), indicating a high level of social cognitive abilities. Scheifele et al. (2015) found that these Asian small-clawed otters can even infer negative (aggression, separation anxiety, pain, hunger) and positive (feeding, training, playing) emotional states of captive otters by pairing vocalizations to social context and circumstance. Overall, the complexity of vocalizations across the Mustelidae, interactive with group-living and degrees of social integration within groups, may support the social intelligence hypothesis (Leuchtenberger et al. 2014); although recent re-analyses have cast doubt on the robustness of the “social brain” hypothesis

(Dunbar 1988), where earlier work was heavily biased by encephalization traits among canids, and neglected extinct species (Finarelli and Flynn 2009).

Aside from communication, ability to detect sounds also serves to warn mustelids of danger. Clinchy et al. (2016) used experimental sound playbacks to observe that European badgers exhibited increased vigilance and reduced foraging on artificially provisioned sites when the sounds of bears and dogs (but not wolves) were broadcast. Crucially, the sound that caused badgers greatest anxiety was that of people talking, suggesting a learned fear of humans when prone to persecution.

### Smell and Taste: Chemoreception

Mustelids rely extensively on scent, and many have a functional vomeronasal organ (VNO) (Kitchener et al. 2017), although the VNO has not been investigated systematically across species. Signals from the VNO are processed in a discrete, but tiny (0.15% by volume), part of the olfactory bulb of the anterior brain. The VNO is often used in detecting the reproductive status of conspecifics, where animals generally lick scent marks, such as urine or glandular secretions, to take up nonvolatile semiochemicals, which are then transferred through the typical flehmen behavior into the VNO (e.g., European badger: Tinnesand et al. 2015).

In parallel to their acute sense of smell, mustelids exhibit a multitude of scent-marking behaviors, and many species have been confirmed to recognize individual conspecifics from their olfactory profiles (reviewed in Buesching and Stankowich 2017). Interestingly, in scent provisioning experiments in the field, European badgers have even been shown to react differently to anal and subcaudal gland secretions of conspecifics according to the spatial context in which they are provided. This highlights an acute socio-spatial awareness. If, for example, scent from a badger belonging to a neighboring group was positioned at the territorial border between the respective groups (i.e., “in context”), scent marks were largely ignored, whereas if the same scent was positioned “out of context” at a border

latrine with a different social group, the scent was frequently investigated and overmarked (Tinnesand et al. 2015).

The hierarchical group structure of giant otters, with a dominant breeding pair, and sometimes as many as 20 subordinates present, leads to some very directed scent-marking behavior, showing cognizance of social status in relation to sexual status and territorial defense. Leuchtenberger and Mourao (2009) report that 62% of marking was performed by alpha males, followed by alpha females. Almost half of alpha male scent-marking events involved overmarking of other group members, but only one-third of those from alpha females were deposited as overmarks, specifically focused on other females. Interestingly, these observations reflect object-marking patterns in European badgers although no obvious dominance hierarchies are evident in this species (Macdonald et al. 2015).

Taste reception has generally received little attention among scientific studies. While strict carnivory results in a fairly stenophagous diet, more generalist euryphagous species, common among the mustelids, must be able to discriminate between different food types and qualities, implicitly through recognizing flavors. A trainable cognitive link between smell and taste has been developed in the context of conditioned taste aversion for the European badger (Baker et al. 2007). Nevertheless, as predicted by the encephalization theory, proposing that carnivores following a strict predatory diet need more brain power than those with an omnivorous diet due to the challenges of capturing live-prey (Gittleman 1986), badgers proved to be comparatively difficult to dissuade to consume certain foods. Trialing three irritants, Cinnamamide, Capsaicin, and Ziram, Baker and Macdonald (2015) discovered that badgers continued to eat familiar food baits, despite these foul tastes (Macdonald et al. 2015). Notably, some individuals were much more persistent than others. Only Ziram acted as a successful deterrent and even then only gradually. By night seven, badgers began to reject baits without tasting them, presumably based on the smell of Ziram alone – where this most likely occurred through second order conditioning to the odor cue.

Exploiting this association, Baker and Macdonald (2015) developed a conditioned taste aversion by presenting an odorless form of Ziram along with pungent clove oil. This combination could produce learned aversion to even untreated baits in the presence of the clove odor cue.

A similar example of instrumental learning has been observed in sea otters. Kvitek et al. (1991) showed experimentally that sea otters actively reduced their capture and consumption rates of butter clams (*Saxidomus giganteus*) high in saxitoxin (the causal agent of paralytic shellfish poisoning resulting from dinoflagellate blooms), or discarded highly toxic clam siphons and kidneys. This behavioral response is likely highly adaptive, given the importance of butter clams in sea otter diets even in areas where toxic dinoflagellate blooms occur.

### Touch: Somatoception

Mustelids use their whiskers (vibrissae) to fine-tune their navigation, or position within confined spaces. Vibrissae are particularly abundant, and rather stiff, among river otters, which may aid in foraging in murky water (Carss 1995), resulting in an expansion of the coronal gyrus in the brains of *Lutra* and *Pteronura* (Radinsky 1968). In contrast, *Aonyx*, and, in a different way, *Enhydra*, exhibit an enlargement of the primary somatic sensory projection area which is associated with the forelimb, indicating increased tactile sensitivity of the hand in these otter species, which reflects their above-mentioned ability to manipulate rocks as tools to pound open shellfish (see above). The American badger (*Taxidea taxus*), in contrast, has high densities of tactile nerves in the lips, nose, and paws, which are likely a functional adaptation for poking through substrate with their noses when digging (Bourlond and Winkelmann 1966).

Having thus far explored the physiological adaptations and constraints acting to focus the cognitive abilities of mustelids, and how their senses of perception relate to their behavior, we next explore how key life-history factors contribute to the way they think and interact with each other and their environment; noting that the more sociable the species concerned, the more

specialized the ethology involved (Holekamp and Benson-Amram 2017). These social interactions, and thus also the cognitive abilities of mustelids, however, are not only influenced by their anatomy, but particularly also by their formidable temperament. Their renowned fierceness is exemplified by honey badgers and wolverines; but even a 100 g weasel can prove a formidable adversary if caught inadvertently by an unsuspecting researcher performing a rodent survey. Macdonald and Newman (2017) speculate that this ferocity may arise from a type of “eco-physiological inertia,” limiting sociability among the mustelidae: many mustelids (e.g., badgers) can use adaptive torpor to cope with periods of food scarcity, where they rely upon high levels of the hunger-alleviating hormone leptin, which in turn stimulates catecholamine secretion (Rousseau et al. 2003). Because inhibited ability to oxidize catecholamines speedily among men carrying the monoamide oxidase A gene mutation is associated with the aggressive “warrior gene” personalities (McDermott et al. 2009), this led Noonan et al. (2015a) to propose that this biochemical pleiotropy might foster fearlessness in mustelids. Along similar lines, several mustelid species exhibit degrees of delayed implantation, which requires the inhibition of oxytocin, the affection, or “antipsychotic,” hormone (Douglas et al. 1998), possibly to the detriment of a sociable nature (Caldwell et al. 2008).

## Diet and Foraging Behavior

Cognitive abilities play a direct role in selection pressures governing the acquisition and consumption of key food resources (McLean 2001). Unable to figuratively “run with the pack,” predatory mustelids tend to be solitary, limiting the opportunity for direct social behaviors to manifest. Cooperative hunting is thus rare among the mustelids; indeed, even when high prey patch richness causes individuals to aggregate, there is scant evidence of musteloids hunting collaboratively – largely because they can dispatch their small prey without assistance. It is likely only the giant otter that is the true cooperative

hunter among mustelids. Although giant otters can hunt alone successfully, groups have been seen to corral fish to improve hunting efficiency (although this has not been quantified), and to tackle prey that they could not manage alone, such as juvenile black caiman (*Melanosuchus niger*) and anacondas (*Eunectes murinus*) (Ribas et al. 2012), apparently able to anticipate the role conspecifics will play in the pursuit and understanding the benefits to collaboration.

Nevertheless, omnivory and opportunism also require memory skills, the ability to weigh multiple criteria, and well-developed declarative maps of foraging ranges (Tversky 1993). For instance, unprecedented cold and snow in subtropical China in January–February 2008 caused yellow-throated martens (*Martes flavigula*) and Chinese ferret badgers (*Melogale moschata*) to shift from a typical seasonal diet dominated by fruit, which still remained available, to consume more small mammals (Zhou et al. 2013) – showing an understanding of the need to increase protein consumption during cold conditions.

Even dietary specialists exhibit keen cognitive abilities linked to foraging success. European badgers mainly eat earthworms in the UK, and research by Stewart et al. proposed that rather than latrines between social groups acting as defensive borders, badgers were instead making “notes to self” marking the isopleth of peak earthworm availability; apparently cognizant that beyond that point badgers foraging toward them from the neighboring group would have diminished earthworm availability (Macdonald et al. 2015).

This European badgers research also provides an example of conditioned foraging responses. In a pilot experiment where food was concealed under paving slabs, to slow down consumption and permit social interactions to be observed (Macdonald et al. 2015), badgers came to associate paving slabs with hidden food generally and began excavating patios at residences adjacent to the woodland research site. The strength needed to casually upturn 10 kg paving slabs belies the way in which badgers combine brute force with intellect to solve problems.

An application of similar abilities for spatial reasoning was recorded by the BBC TV series

*Land of the Tiger* (1997), where a honey badger (*Mellivora capensis*) exploring a cave in India rolled a log to where it could use this “tool” to climb up and reach a kingfisher fledgling, lodged among roots in the cave ceiling. Similarly, honey badgers have been seen to relocate objects (logs, rocks, rakes, spades, tires, etc.) to enable them to escape from walled captivity pits. In this amazing display of spatial cognizance, clearly the honey badger was planning repeat escapes through various combinations of items and strategies, and exhibited genuine insight (Sutherland and Mackintosh 2016) into how to solve the problem of scaling a concrete wall.

Of course, the ability to understand orientation and navigation in confined spaces is fundamental to archetypal elongate mustelids, which hunt rodents through tunnels. Relatively little is known about fossorial activity, because it proves difficult to track and study underground behavior (but see Noonan et al.’s (2015b) development of magnetic inductive tracking methods). Clearly, species such as black-footed ferrets (*Mustela nigripes*) can hunt within prairie dog burrows with considerable efficiency (Biggins & Biggins and Eads 2017). Interestingly, Perreault and Plowright (2004) have proven experimentally that ferrets can take short cuts between two points, implying they follow more complex declarative cognitive maps, rather than simple procedural rules. Noonan et al. (2015b) have also redressed the assumption that when European badgers use their setts (burrow systems) by day they are “at rest.” Instead they engage in a variety of underground relocations, often linked to social bonds, implying that they make informed decisions on tunnel and chamber use.

The omnivorous tayra shows highly developed prospective thinking linked to foraging success. It is the only nonhuman mammal reported to cache green unripe fruits, specifically native sapote fruit as well as cultivated non-native plantains, apparently in the knowledge that these climacteric fruits will then ripen (Soley and Alvarado-Diaz 2011). Not least, the different developmental rates of these two fruits require that tayra understand their respective ripening processes. By harvesting unripe fruit tayra gain a selective advantage over

other sympatric frugivores that must wait until fruits are edible. European badgers display a similar understanding of time effects when predating rabbits (Martin et al. 1995). They patrol past rabbit warrens until the kits underground are large enough to provide a substantial meal, but still too young to flee predation, and then dig down to unearth their prey. This involves acute spatial awareness, where badgers do not dig into warrens along rabbit tunnels, but directly into the nesting chamber from above.

Interesting reports of feeding mutualisms among mustelids involve the apparent understanding of the benefits that interspecific cooperation can bring. Most often quoted being the association between honey badgers and honey-guides (*Indicator indicator*). This arose from hearsay reported by Sparman in 1785, and today many consider this a fallacy. Nevertheless, honey badgers have been reported to hunt commensally with black-backed jackal (*Canis mesomelas*) and pale chanting-goshawk (*Melierax canorus*), although without any apparent costs or benefits (Begg 2006). American badgers will also hunt phoretically (accidentally and nonobligatorily) with coyotes (*Canis latrans*) for ground squirrels (Lehner 1981); although the greater benefit is likely to coyotes that chase down squirrels flushed from their underground burrows by the badgers’ excavations (Minta et al. 1992).

Of course collaborations between humans and mustelids also require an advanced understanding of the resultant benefits. Examples are few, but in Sundarbans region of Bangladesh a traditional fishing method involves two trained smooth-coated otters (*Lutrogale perspicillata*) and an immature trainee otter working with three fishermen from a boat. Otters herd fish into a net and greatly enhance capture success – indeed around 2000 people depend on this fishing method for their livelihoods in the region. Even our interaction with the most tractable of mustelids, the domestic ferret, stems from their traditional use by human hunters to help flush rabbits (*Oryctolagus cuniculus*) from warrens (Cowan 1984); again illustrating that ferrets can comprehend complex roles and social relationships.

## Collaborative Behaviors: Den Use, Parental Care, and Cooperative Defense

Cooperative breeding is rare among mustelids, although giant otters present a notable exception (Groenendijk et al. 2017). In this species pups are produced only by the groups' dominant breeding pair, although subordinate nonbreeding adults of both sexes provision these pups with fish. The greater the number of these nonbreeding helpers, the more likely pups will survive. Interestingly, giant otters also appear to care for elderly group members, with Davenport (2010) reporting multiple forms of assistance given to the declining group matriarch. Perhaps this suggests an altruistic understanding of "acquired credit," beyond utilitarian reciprocity.

Despite group living, European badgers do not seem to provide any substantive allomaternal care to cubs (Fell et al. 2006), with cubs being largely left to their own devices when old enough to emerge from the underground sett. One curious and informative facet of badger reproduction involves whether fathers can recognize their own offspring. Certainly, infanticide by males that know they are not related to offspring can be an issue in carnivore societies (Agrell et al. 1998), and so when badger populations reach very high densities strategies to avoid infanticide have a selective advantage. To these ends, high-density badger populations exhibit highly promiscuous and noncompetitive polygynandry (Macdonald and Newman 2017), which combined with 10 months of delayed implantation in this species sufficiently confuses and dislocates mating from birth, so that paternity is confused. To what extent females understand and plan that their promiscuity confuses males is unknown; however, this strategy would be undermined if males could recognize their own offspring in some way, possibly via scent (Porter et al. 1986). In this regard, work by Fell et al. (2006) found that while cubs are still too immature to produce their own subcaudal scent secretion, they anoint themselves with the subcaudal secretion of other adult group members, by ducking under the belly and squeezing out under their scent glands, in what they termed "scent theft."

Relating to this, and likely linked to a lack of reliance on visual senses in musteloids, Buesching and Stankowich (2017) emphasize that, unlike most other Carnivore families, young mustelids lack the distinct neotenic "kindchenschema" that would usually solicit care-giving; those features that cause people to find kittens and puppies appealing.

Because the majority of mustelid species forage alone, and are often disproportionately fierce and thus relatively unworried about threats from predators and competitors (Newman et al. 2005), instances of cooperative defense are few, and largely restricted to the social otters. Certainly groups of giant otters use display and attack to repel rival groups and marauding caiman (Ribas et al. 2012); similarly, Cape clawless otter groups defend against conspecifics. There is even a plausible, if unproven, suggestion that sea otters may attempt to confuse sharks and orca (Hatfield et al. 1998) by forming large rafts.

## Mutual Interactions

Giving care to another individual requires cognizance of the benefits afforded by this generosity. These may be reciprocal, or involve inclusive fitness, or may simply serve just to appease aggression (e.g., Rankin and Taborsky 2009). The possibility of mutual interactions outside of maternal care is again restricted to very few, more social species. Social otters not only play but also allogroom one another, arising from the need to remove ectoparasites (Green et al. 2015). But perhaps one of the most detailed studies of the precise understanding and weighing of reciprocity relates to mutual grooming in paradoxical European badgers, only just on the cusp of evolving secondary benefits from group-living. Badgers groom mainly to alleviate itching from their large host-specific flea, *Paraceras melis* (Cox et al. 1999). When alone, they focus on their chest and belly, but they appear to understand that they must elicit the assistance of conspecifics to de-flea harder to reach areas. Cooperative grooming involves reciprocity, and badgers give very little credit, defecting within just 1.2 seconds if the

recipient does not respond in kind (Macdonald et al. 2015). Once initiated, cooperative grooming bouts continue until one individual defects, whereupon the other generally stops within half a second, in a classic tit-for-tat arrangement. This rather Machiavellian cooperation seems entirely self-serving and evidences a distinct lack of trust or altruism between actors.

Badgers also allomark each other with their subcaudal gland scent secretion (Buesching and Stankowich 2017) to create a shared group-odor. Marking can either be mutual, with two badgers pressing their subcaudal pouches against each other simultaneously to maintain a cohesive group smell, or sequential, with one badger marking the body of another individual, likely as social appeasement as well as an individual advertisement signal, being strongly influenced by sex, age, and reproductive status. Strong correlation in the frequencies of sequential and mutual allomarking, combined with allogrooming, point to particular cliques within broader badger groups of more closely interacting individuals, highlighting that badgers discriminate with whom to invest in socializing.

## Conclusion

When examining the way such a diverse group as the mustelids acquires knowledge, interprets experiences, and thinks about situations, it is difficult not to slip into interpretative bias (Wilder 1996), or to make inferences about their societies flavored by our own human cognitive biases (Harding et al. 2004). How much mental processing power does it take for an otter to catch a fast-moving fish in three-dimensional space? Or for a honey badger to plot an elaborate escape from a zoo pen? Indeed, what fine-tuned cognitive skills are required for a weasel to simply catch a mouse? Even comparing the intellect needed to undertake solitary practical skills is incomparable with the social mind required to deal with group-living situations.

Neurophysiological experimentation can elucidate some of these points, but such studies are lacking for the mustelids. This leaves us to

interpret observations, guided by the certain knowledge that natural selection weeds out inefficiency, and so the cognitive abilities of species are just as highly tuned as their more evident specialized anatomies. What is clear is that whatever the mustelids do, they do it well, with ecological niches spread far more widely than in any other carnivore family; arguably more diverse than in any other mammalian taxa.

### Feeding habits

## Introduction

Diet is one of the most important dimensions of the ecological niche of an animal (Hutchinson 1959). Knowledge of the feeding habits of an animal allow us to understand how it deals with the food available in the environment, and how it changes in space and time as a function of fluctuations and distribution of food resources, in terms of the stability and predictability of the environment (Kruuk 2006; Ruiz-Olmo and Jiménez 2009). Within the Carnivores, as is the case of the Mustelids, the abundance, quality, and distribution of food has a first order of importance in body condition, survival, reproductive capacity, socialization, and size of the groups, as well as to determine the use of space and time and home range size, among others (see also Gittleman 1989; King and Powell 2007).

Mustelid energy needs (basal rate and food) are 20% higher than those of other terrestrial Carnivores (McNab 1989). According to this author, the energy needs of otters (subfamily *Lutrinae*) are even 20% higher than those of other terrestrial representatives of the mustelids. Thus, Mustelidae constitutes a group in which obtaining a sufficient and quality food is of great importance. For instance, Kruuk (2006) considers that Eurasian otter *Lutra lutra* is food-limited species, as it is the case of the other species of otters, mainly in high mountains or colder waters.

Food acquisition can be understood as an active process where the animal chooses from the different available resources. The comprehension of how a species choose from the available prey is very important to conservation biology, and habitat and species management, once it allows the selection of priority areas and the elaboration of conservation plans and the recovery of degraded areas (Miller et al. 1996; Manly et al. 2002).

The Mustelidae is the largest and the most diverse family of the order Carnivora. The 59 recognized species (following Wilson and Reeder 2005), also called weasel-like family, are widely distributed through all continents besides Antarctica and Australia. They show great variation in size (from 30 g to 40 kg) and can occupy nearly

every habitat, both terrestrial (subdesert, burrow, arboreal, humid, snow-covered, and agricultural), aquatic (salt and fresh water), and even man-made or urban (Griffiths 2000; Nowak 2005; Wilson and Mittermeier 2009). Not surprisingly, with this wide range of habitats and body length, the mustelids present a wide range of feeding habits, ranging from omnivory to strict carnivory, from terrestrial to aquatic prey, from living animals to carrion. Mustelids are agile, usually are flesh hunters, feeding mainly on mammals, birds, amphibians, reptiles, fish, crayfish or crabs, and molluscs or insects. Some mustelids can feed on plants, fruits, eggs, honey, and be omnivores (Nowak 2005). Most of them eat nothing but meat, with teeth highly adapted to predation and to dilacerate their prey (Macdonald 1995).

The plasticity in the feeding behavior, with a wide niche breadth, is one of the reasons that helps to explain their huge distribution range (for examples, see Clevenger 1994; Martin 1994; Clavero et al. 2003; López-Martín 2006; Ruiz-Olmo and Jiménez 2009; Zhou et al. 2011; Rheingantz et al. 2017). Even within the same species, the diet may vary spatially or temporarily according to the prey and food available. There are some exceptions of this plastic behavior, as in the case of the endangered black-footed ferret *Mustela nigripes* (Miller et al. 1996; Belant et al. 2015). This ferret feed mainly upon prairie-dogs, depending of habits occupied by those rodents as they also depend of their burrows for shelter and denning (Ludwig et al. 2008). This is often also the case of the least (*M. nivalis*) and long-tailed weasels (*M. frenata*), and the stoat (*M. erminea*), often depending on one-two rodent species (King and Powell 2007).

The diet of Mustelids is heavily affected by the abundance and biogeography of their prey as was demonstrated for otters and martens (Clavero et al. 2008, 2003; Clevenger 1994; Martin 1994; Rheingantz et al. 2017; Ruiz-Olmo and Jiménez 2009; Zhou et al. 2011). Mustelids prey on a wide trophic spectrum, which depends on the temperature. In warmer areas, mustelids presents wider niches and prey more often on plants, fruits, insects, fish, and reptiles, while in the colder areas, the main preys are carrion, mammals, and

birds. In the case of otters, marine and estuarine habitats provide the wider prey species availability, resulting in the wider trophic niche width (see Kruuk 2006).

### Strategies of Food Acquisition by Mustelids

The mustelids, as opportunists and occupying wide range of environments, adopt many strategies of food acquisition, depending on the habitat and prey types available. They have slim fusiform body shape, short legs, often very long tail and well-developed senses that work well both in aquatic and terrestrial environments, as vision, hearing, smelling, and touch. There are several species of mustelids that are semiaquatic; they forage in the water but also depend on the land to rest and breed (Dunstone and Gorman 1998). There are degrees of water dependence, but semiaquatic mustelids usually catch their food from the water, by swimming or diving. Otters, for example, prey mainly upon aquatic animals as fish and crustaceans but can also prey upon amphibians and other vertebrates and invertebrates (Dunstone and Gorman 1998; Kruuk 2006). Due to its dependence for both environments, terrestrial and aquatic, semiaquatic mammals, as the otters, some polecats and minks, occur mainly alongside rivers, streams, lakes, bogs, marshes, lagoons, coastal zones (Kruuk 2006), and even reservoirs. River otters and minks use their vibrissae and vision to locate prey movement underwater (Dunstone and Gorman 1998), either during the day or at night. The semiaquatic mustelids are considered single-prey loaders, catching one prey per dig (Houston and McNamara 1985), and they usually prey in shallow water to enhance the searching efficiency of prey. As they are not so adapted to the water as the otters, minks can locate a part of their prey outside the water to maximize the success rate in catching it (Dunstone and Gorman 1998). These animals are found close to rivers or small pools, or near the surface in open areas, in places with higher densities of prey and where the prey are easier to catch (Kruuk and Moorhouse 1990).

The 13 species of otters are top-chain predators that forage mainly on the water, looking mainly for aquatic prey (Kruuk 2006). The

river otters encompass 11 species. Four of them live in groups, in part or all the year. As they forage in groups, they predate upon fish clusters and they can catch bigger fish than other species that usually forage individually. The group besiege the prey shoal, make a semicircle, and each animal catch its prey by itself. The smooth-coated otter forage in groups, with everyone having its task to help in the hunt. The South-American giant otter *Pteronura brasiliensis*, the longest mustelid, that can reach two meters long, are also social, that forage in groups. However, differently from the Asian smooth-coated otters, each animal usually hunts by its own prey lonely. They can predate in groups when chasing large and dangerous preys as black caiman, as occurs in Brazilian Pantanal, even though they usually do not share it.

Most of river otters are solitary animals and look preferentially for slow mobility prey such as suckers, cyprinids, cichlids, salmonid, eels, catfish, crayfish, and crabs, but they can prey upon other aquatic invertebrates (i.e., molluscs), anurans, snakes, or aquatic insects (Kruuk 2006) when they become more available or easier to catch in relation to fish. They can also prey in coastal shallow waters and river margins and pools, using their touch, hearing, and vision when possible to locate prey underwater.

The teaching process is very important in Carnivores, and the mustelids are not an exception of it. The parents, and the brothers when they are social, teach the juveniles how to hunt. For the semiaquatic otters, they teach how to dig and to prey underwater, for example.

An interesting behavior was observed for both Eurasian and Neotropical otters: the predation upon toads (*Bufonidae*). These animals have toxins in their skins produced by the serous glands, mainly in the back and head. When preying upon toads, the otter start eating them by slicing the ventral part and skinning to avoid the contact with the toxins. This behavior appears to be innate, once captive Eurasian otters that never saw a toad before show the same behavior as the wild ones (Morales et al. 2015).

There are two otters that live exclusively in salt water environments: the sea otter *Enhydra lutris*,

in the Northern Pacific, and the marine otter *Lontra felina*, in the Southern one (Doroff and Burdin 2015; Kruuk 2006). The sea otter usually dives in waters with less than 30 m in depth to look for its prey (Estes et al. 2003). As it lives in cold waters, it spends a lot of daily energy intake (eats 20% of total body weight daily) just to maintain the body heat. This mustelid is a kelp-system top-chain predator that digs up to 4 min looking for its prey. When it comes to the surface, it uses a tool, usually a stone, to break the hard parts of sea urchins, mussels, crabs, and clams. Each animal carry its own stone in the hind foots during the period it does not use the artifact (Kuuk 2006). *L. felina*, however, lives on the shore and around, looking for prey as freshwater otters do. Some “inland” otters inhabit coastal habitats as *Lutra lutra*, *Lontra canadensis*, *L. longicaudis*, or *L. provocax*, foraging and catching the prey both in the shore in shallow waters and diving in deeper waters as sea otter does (Kruuk 2006).

Among the terrestrial species, there is also a great variety of strategies. The wolverine *Gulo gulo* lives in low-productive tundra/taiga zone habitats of northern Holarctic and is active all year around. The species is the largest terrestrial mustelid (Nowak 2005), and is polyphagous. In the winter, some of these animals use their excellent smell to feed mainly upon carcasses of large herbivores as reindeers and caribous that die in avalanches or during cold winters (Lofroth et al. 2007). They can be also an active predator, capturing also deer.

Due to their agility, high metabolism and strong bite, weasels can prey upon animals with larger sizes than themselves. The weasels, polecats, and ferrets (least, long-tailed, stoat, black-footed ferret, European, steppe, and marbled polecats, for example) can eat preys with two or three times its size, as voles, rats, lemmings, prairie dogs, rabbits, or ground squirrels (King and Powell 2007). These animals can hunt underground or inside the snow (burrows, tunnels, stone, and rocky habitats), and by using the smell and touch, they forage both during the day and at night. A common hunting strategy of these animals is to follow their prey to their holts or burrows, killing and eating them inside there.

The stoat is a fast-opportunistic predator that looks for preying inside burrows and is also good climber. These characteristics allow it to prey upon bigger rodents and lagomorphs, and birds and eggs in nests. The weasels, stoats, and ferrets commonly bite the prey on the back, by the spine/throat.

The martens are medium-sized carnivores that are good climbers, some of them climbing mainly on trees (American marten, pine marten, yellow-throated marten, Japanese marten), but some climb rocks, stones, or even buildings (stone marten). They are opportunistic species with a wide trophic spectrum, including a high consumption of fruits in summer, autumn, and even winter (Clevenger 1994; Martin 1994; López-Martin 2006). They are also very good hunters, having a strong bite that immobilizes the prey at the back of the throat. In the case of fruits, martens look for trees or bushy areas during the appropriate season. In this case, they can take fallen fruits from the ground or climb on the trees and take directly the fruits.

The fisher is a “large marten” that displays an interesting behavior to prey upon porcupines, by biting their faces several times when the prey is cornered. The fisher starts to consume the prey even alive, once it is immobilized.

Grisons (genus *Galictis*) are good climbers and swimmers but are mainly terrestrial predators. During the hunting, the grison moves in a zigzag pattern and can prey as a cat, moving silently with the body very close to the ground.

The badgers use their long claws and strong jaws to hit the prey; the European badger is one of the few species that can prey the hedgehog. As they are very good in digging and have good smell, most badger species look for earthworms in habitats plenty of them, caving holes on the earth. As the martens, badgers also look for fruits rich patches, but they cannot climb up trees or high bushes.

### Variation in Feeding Habits within Mustelids

With practically 60 mustelid species, and living in practically all kind of habitats, this family presents an enormous variety of feeding patterns. However, there are some few general strategies, all of

them involving the capture of animals as must be expected in a carnivorous origin group:

- Omnivorous, eating animals (vertebrate and invertebrate), fruits, honey, and other (martens, sable, badgers, ferret-badgers, tayra, grisons)
- Strictly carnivorous, eating mainly mammals (weasels, including Patagonian; stoat; ferrets; fisher; wolverine)
- Strictly carnivorous, eating mainly aquatic or semiaquatic preys (otters)
- Strictly animal eaters, but wide spectrum including insects, crustacean, amphibian, and other (polecats, minks, zorillas)

Among the omnivorous, the martens *Martes* sp. are medium-sized carnivores that occur in boreal and temperate habitats of the Northern Hemisphere, being distributed widely over the Holarctic. They show broad habitat flexibility, occupying several types of habitats, what is reflected in the plasticity of their feeding habits, where small mammals (principally rodents), fruits, and insects provide primary or secondary food resources (Clevenger 1994; Martin 1994; López-Martin 2006). As expected for opportunistic animals, as many other mustelids, they show differences in the diet between areas and even seasons. When the main prey becomes scarcer, martens change their main prey to another. Temperature, rainfall, and other factors can affect the ecosystem dynamics, what changes the prey availability and consequently the diet of *Martes* sp. (Wilson and Mittermeier 2009). Northern martens consume large amounts of carrion in winter and spring time (Clevenger 1994; Selva 2004).

The badgers (genera *Arctonyx*, *Taxidea*, *Meles*, and *Melivora*) inhabit both pristine and farmland habitats, and even cities (Wilson and Mittermeier 2009). The broad habitat types occupied by those animals can be justified by the broad niche of badgers. They are generalist omnivores that eat vertebrates, invertebrates (worms, insects), cereals, fruits, roots (honey), and even snakes. As generalists, they have different primary food sources between regions. The European badger *Meles meles* eat primarily earthworms in humid

habitats, but in some human-modified locations, the species can increase the ingestion of cereals and fruits. In more forested areas, with great availability of fruits and insects, those items were consumed more frequently by the badger, while in open areas the rodents or lagomorphs are preferentially eaten. The honey badger *Melivora capensis* can vary the diet between seasons, maintaining daily intake in weight, but switching items and varying niche breadth from summer to winter. The exception of this generalist behavior of badgers is the American badger (*Taxidea taxus*). This badger is specialized in rodents as prairie dogs and squirrels in many areas (as the European badger in some areas). The predator excavates the burrows of the prey and preys it inside the hole. Some of them can store the prey not eaten immediately to consume later.

The tayra *Eira barbara* is another opportunistic polyphagous omnivore, with a very diverse diet, including fruits, vertebrates, and also carrion. It can also prey upon insects and feed honey, being called in Portuguese as “papa-mel,” which means honey-eater. Its plastic behavior is probably associated with the wide variety of habitats that the tayra occupies, from forests to disturbed areas. The knowledge of the feeding habits of this mustelid rises from opportunistic observations, without a systematic study aiming to describe the seasonal and spatial differences in its diet. Its predation upon mammals, reptiles, and birds and the consumption of coffee, mamey, palm, genipapo, and *Cecropia* were reported.

The grisons, genus *Galictis*, are agile hunters, swimming and climbing very well. The lesser grison *Galictis cuja* preys mainly upon small mammals but can also eat birds, reptiles, amphibians, and their eggs. There are few studies focusing in its diet, but the main preys of the species seem to be rabbits and hares (Delibes et al. 2003). This behavior of predating upon invasive species can hire the species as a potential biological control of these two Lagomorph species. The greater grison *Galictis vittata*, as the smaller one, is opportunistic, eating almost everything it can obtain from predation. The main preys are small-medium sized vertebrates as agoutis and other rodents and lagomorphs, but

it can prey upon birds, lizards, amphibians, and their eggs too.

Weasels and ferrets can eat different vertebrate species, but they prey specially on small mammals, from mice or voles to rabbits and marmots (King and Powell 2007).

More aquatic the animal, more dependent from aquatic preys, as shown by the differential dependence of the sea otters, river otters, minks, and polecats for aquatic preys (Wilson and Mittermeier 2009). The most aquatic mustelids, the otters, prey mainly upon aquatic animals. River otters as Eurasian and Neotropical otters are generalist predators that show variation in their diet between areas and seasons. They prey preferentially upon fish, crustaceans, and frogs. Usually, fish constitute the main prey, but in certain areas and seasons, in situations with limited fish abundance or with restriction to small-sized fishes, or even with high availability of alternative prey, the otter can change the main prey to crustaceans, toads, frogs, or other aquatic species. More dependent on the terrestrial environment, minks *Neovison vison*, and *Mustela lutreola* eat aquatic prey, but less frequently than otters. They can prey upon aquatic birds as the water fowl and small mammals as rabbits and rodents. Polecats *M. putorius* are the most terrestrial of these three Mustelids, and they prey mainly upon terrestrial prey as woodland rodents and rabbits, and anurans are also common. These differences allow these Mustelids species to coexist in the same region, with exception of the two minks. The invasive American mink is a better competitor than the native European one, and in areas where they coexist, usually the European mink end up disappearing.

The sea otter *Enhydra lutris* can live all its life inside the water. Not surprisingly, it preys exclusively upon aquatic prey. They are top-chain predators of kelps and can prey upon several animals, but the main preys are benthic invertebrates as sea urchins, abalones, and mussels and clams. The Neotropical otter *Lontra longicaudis* and the giant otter *Pteronura brasiliensis* coexist in parts of their distribution. In those areas, although preying upon aquatic slow-mobility prey, they hunt different animals and with different sizes. The giant otter has a narrow food niche,

preying upon larger prey, mainly fish with 20 cm size or more. The Neotropical otter has a wider niche, preying on smaller fish (10–15 cm) and other categories of prey as crustaceans and anurans.

### Differences of the Diet between Size, Ages, and Sex of Mustelids

Most of the mustelid species present sexual dimorphism, the males being larger and heavier than the females (Holmes and Powell 1994; Kruuk 2006; King and Powell 2007). This provides different opportunities due to differential feeding specialization. This situation is more extreme within weasels, stoats, ferrets, and polecats, displaying differences in the type of species taken and in the prey size, between both sexes (King and Powell 2007). This can be a strategy to avoid intraspecific competition, especially during food shortages and to prevent the affection or event depletion of food stocks. There are other mustelid species that present differences in prey choices between sexes. As for example, in Shetland, UK, the Eurasian otters show differences in the feeding habits of solitary females, females with cubs, and adult males (Kruuk 2006). Usually, the males eat larger fish than females and cubs.

It was observed in Canada that mountain wolverines also show differences in the diet preferences between sexes (Lofroth et al. 2007). During the winter, females usually prey upon smaller animals, while larger males prey upon large ungulates as reindeer. Also, differences within sexes were observed. Caribou, hoary marmots, and porcupines were found in significantly higher frequencies in the diet of reproductive females than other females. However, there are exceptions. Despite marked sexual size dimorphism, male and female honey badgers do not show differences in daily intake and prey sizes (Wilson and Mittermeier 2009).

Mustelids also present differences in diet among age classes. This is the case again of the Eurasian otters in Shetland islands (Kruuk 2006). Cubs eat larger prey (more mass carried in a single way) during the first months of life than mother.

The type of prey consumed may be learnt from the parents, what explain the complex strategy

adopted for predation. In California sea otter, individuals from the same population specialize in different food items, with this behavior being passed from mothers to sons (Estes et al. 2003). The sons hunt in the same way as their mothers, with the main prey being the same.

## Conclusion

In this chapter, it was described how the mustelids get food from different sources and what are the main food items in their diets. They are usually highly mobile generalist predators that have different strategies depending on the environment where they occur. The animals of this highly diverse family can also feed upon fruits and other vegetables, honey, and can predate upon several species of animals, from aquatic to terrestrial ones. The comprehension of how each Mustelidae species deals with the food available, being more specialist or generalist, many times helps to adopt right strategies for its conservation. The black-footed ferret, one of the most specialist Mustelids, experiences conservation challenges, as it only occurs where its main and almost unique prey occurs, the prairie dog (Miller et al. 1996). Conservation decisions must consider the flexibility in habitat use and diet to project how the species would deal with food shortages and habitat modifications.

## Mustelidae Life History

Carolyn M. King

University of Waikato, Hamilton, New Zealand

## Synonyms

Delayed implantation; Reproductive strategies; Weasel family

## Introduction

The Family Mustelidae includes a diverse group of small-to-medium-sized carnivores, adapted to a wide range of habitats and distributed worldwide. The 22 genera and 59 species range in body size from the least weasel (*Mustela nivalis nivalis*, 30–70 g), the smallest living carnivore, through the martens and sables (*Martes*, 0.5–5 kg), river-otters (*Lutra*, 5–30 kg), and badgers (*Meles*, *Taxidea*, 2–12 kg), to the bear-like wolverine (*Gulo gulo*, 25 kg) and the sea otter (*Enhydra lutris*, 45 kg).

The latest (Koepli et al. 2008) phylogeny of the family has identified four major clades (otters, weasels, martens, and galictids) plus three separate lineages of badger-like animals, mostly originating in Eurasia as a result of two bursts of diversification during the Tertiary era. The first, about 12–9 mya (million years ago) was

correlated with a global change in faunal composition as climate cooled, forests retreated, and the grasses evolved; and the second accompanied the start of the glacial cycles at about 5–2 mya. The earliest of the living lineages to reach the New World (extinct American badgers) arrived in the Miocene (about 7 mya) via the Bering Land Bridge.

These diversification events were set off by major environmental changes driven by the cooling climate, e.g., the spread of vast dry grasslands and the evolution of the voles and lemmings. These changes created new ecological niches determining the type and distributions of prey for mustelids, and correspond with similar events in other vertebrate groups. The global diversity of living mustelids is due to repeated dispersal from the Old World south to Africa and east to the New World, followed by local adaptation.

The Mustelidae as a group offer a clear example of adaptive radiation, defined as the evolution of multiple lineages of descendants adapted to different lifestyles and habitats, all traceable back to a common ancestor in the Oligocene (before 24 mya). The smallest species form a size-graded set of co-existing small, specialized searching predators, which share habitat and morphology but partition prey resources by size. At the other extreme, the larger species are generalized predators, dissimilar in morphology because of their advanced adaptations to different arboreal, aquatic or fossorial habitats. Body size is one of the most important parameters linked to life history characters; hence, we can observe an unusually wide range of life history characters within this one family. Complicating these general patterns is the fact that all members of the Mustelidae have some degree of sexual size dimorphism, whereby the males are larger – in the smaller species, much larger – than the females.

### Body Size, Habitat, and Population Dynamics

Body size, habitat, and the interaction between them profoundly influence life history and

population dynamics. Size affects energy requirements, metabolic rate, reproductive effort, generation time and population rate of increase, and therefore also home range and population density.

Habitat can be defined as that part of the total environment available to the individual (King 1983) and for carnivores the most important aspects of a habitat are the type and extent of vegetation cover, which determine the species and distribution of prey. For example, a strip of long grass full of field voles (*Microtus* sp.) may offer a short-term habitat for a weasel, which its offspring will probably have to leave. By contrast, a whole woodland and many of the surrounding fields may be a stable and permanent home for generations of badgers (*Meles meles*). Hence, mustelids of different sizes must have different life-history characters and population dynamics even when sympatric (King and Moors 1979).

When considering life histories, it is useful to make a distinction between evolutionary and ecological time. At the species level, life histories have evolved over millions of years and can be labelled as long-term *strategies*. In this context, the term “strategy” does not imply any forethought or planning; it simply describes the predictable results of a coordinated assemblage of reliable species-specific characters (e.g., average age-specific fertility and survival rates, and life expectancy) which are generally not changeable by individuals. The most important factor determining long-term life-history strategy is habitat stability.

But within those strategies, there is room for some flexibility at the individual level to variable environmental conditions. Short-term individual responses changeable in ecological time can be labeled as *tactics*. A similar contrast between long-term and short-term effects is summarized by the comment that: “Climate is what you expect; weather is what you get.”

### Life History Strategies

In short-lived and changeable habitats, the living conditions enjoyed by successive

generations may be very different – for example, in boreal grasslands and tundra, where voles and lemmings go through 3–4 year cycles of numbers ranging from sparse to super-abundant. In such a precarious environment, natural selection has favored the combination of reproductive characters which most strongly increase  $r$ , the population rate of increase, so they are called “ $r$ -selected” or “opportunistic” species. The key characters of such species are: early maturity, large litters, more than one litter per year, small young, minimal parental investment, short period of learning before independence, and a short average life span, in that order. Opportunistic species typically have small body size, short generation time, unstable populations, high and variable annual mortality and dispersal rates, and considerable resistance to total (though not to local) extinction. All the smallest mustelids are solitary and strictly carnivorous (King and Powell 2007).

By contrast, in long-lived and stable habitats such as a climax forest or undisturbed major waterways (preindustrial rivers, lakes, and the sea), the living conditions for successive generations are likely to be broadly similar. Forest predators such as pine martens, fishers, and sables, and for aquatic species such as river-otters and sea-otters, depended, for much of their evolutionary history, on broader food supplies less liable to feast-or-famine fluctuations. Some, e.g., stone martens and badgers, are omnivorous, extending the breadth of their dietary options. In such a (relatively) steady environment, natural selection has favored the combination of reproductive characters which most strongly affect  $K$ , the population density, so they are called “ $K$ -selected” species. Their key characters are (compared with  $r$ -selected species): later maturity, smaller litters, only one litter per year, large well-developed young, maximal parental investment, long period of learning before independence, and a long average life span, in that order. Equilibrium species typically have larger body size, longer generation time, stable populations, low annual mortality of adults, and greater vulnerability to extinction. Where the net marginal benefits of mutual association exceed the costs of

competition, some of the larger mustelids, e.g., European badgers and giant otters, have become sociable.

Of course, there are all gradations between these extremes, so there is a recognized  $r$ - $K$  spectrum of selective advantages generally correlated with reproductive effort, even though the combinations of life-history characters are somewhat flexible. This effect can best be seen by examining a set of sympatric species belonging to one mustelid assemblage. For example, the six members of the family Mustelidae resident in Britain can be ranged along the spectrum, as shown in Table 1. Similar tables could be compiled for other mustelid assemblages.

### Life History Tactics

The key challenge for all breeding animals is to minimize the risks of leaving no surviving young, thereby failing to pass on copies of their genes (King et al. 2003). Opportunistic and equilibrium species tend to use different tactics to respond to this problem. For parent animals belonging to opportunistic species, the chances of producing surviving young range from very high to practically nil, depending on the fluctuations of resources during the current breeding season and the dispersal capabilities of their offspring.

By contrast, for parent animals belonging to equilibrium species, the chances of success depend more on their social position within an established population, which in turn determines whether they can maintain possession of a viable territory and produce strong and competitive offspring.

Specialist vole predators such as least weasels face the greatest variation in resources between years, because the population fluctuations of their primary or only prey create alternate feasts and famines over periods longer than the average life span of breeding adults (1–2 years). In such a precarious environment, the best chances of parent weasels achieving reproductive success are to make a great effort to produce large numbers of small young capable of growing rapidly, dispersing widely and maturing quickly enough to

**Mustelidae Life History, Table 1** Relative positions of native British mustelids along the r-K spectrum, from strongly r-selected at left to strongly K-selected at right. Figures in parentheses following a mean give the range;

figures in square brackets are rough estimates. (Adapted from King and Moors 1979, updated from Harris and Yalden 2008)

produce their own offspring at an early age. Young female least weasels born in the spring of a year with abundant voles are the only members of the Family Mustelidae capable of mating in the summer of their birth (at 3–4 months old), while at the same time, their mothers can produce a second litter. The combination of good juvenile survival and summer litters borne by both mothers and their early-born young results in a sudden huge increase in least weasel numbers at the peak of the vole cycle. During vole crash years, the local population of least weasels simply disappears, until restocked by young wanderers dispersing from more favored habitats elsewhere.

By contrast, equilibrium species have fewer options. Martens, otters and badgers take longer to mature and produce fewer, larger and slower-growing young. None can breed more than once a year (Table 1). Their best chances of achieving reproductive success are to produce small numbers of strong and well educated young capable, once mature, of competing with resident adults for social acceptance and living space. For established adults, the chances of living through more than one breeding season are relatively good. In years when few young are likely to survive, a resident adult can reduce the number

of young in a litter, or even skip breeding altogether, meanwhile holding on to their territory. For the parent, it is a better tactic to save wasted effort this year if there is the chance of better luck next year, so the parents put less effort into each litter. Variation in juvenile survival still causes fluctuations in population density, but over a smaller range than in opportunistic species.

This general pattern can be illustrated from the density data for mustelids recorded on Polish farmland through a population irruption of field voles in 1970–72 (Ryszkowski et al. 1973). The numbers of voles were low but increasing in the winter of 1970–71; they peaked during the summer of 1971, and the decline started in the winter of 1971–72. During this time the density of weasels varied threefold (15–46 hectares per weasel); the density of pine martens varied twofold (221–443 hectares per marten); and the density of European badgers remained at 510 hectares per badger throughout. Such contrasts in population density are due to age-specific variation in fertility and survival in all species, but the variation is controlled differently: by food resources in opportunistic species, but by density-dependent competition and social status in equilibrium species.

## Delayed Implantation

Of the 59 species in the family Mustelidae, the life history patterns of at least a third include some form of delayed implantation (DI), compared with 0.05% of all mammals (Thom et al. 2004). Under DI, the normal progression of reproductive processes from fertilization to birth is interrupted by a period of diapause (suspension of development). The fertilized zygote develops as far as the blastocyst stage, a hollow ball of cells, but it cannot implant until the uterus is ready to receive it and to cooperate with it in establishing a placenta. So the blastocyst simply floats free in the uterus, for periods varying from a few days in American mink to 10 months in the stoat. Only after a complex series of signals are exchanged between uterus and blastocyst can implantation and development proceed in the usual way. The period of delay therefore lengthens the reproductive cycle by disconnecting the season of mating from the season of littering.

DI is distributed patchily through the family, and is not a simple correlation with *r* or *K* type population dynamics. For example, of the six species ranging along the *r*-*K* spectrum shown in Table 1, three have periods of delayed implantation of different lengths, and three do not have it at all. Habitat and environment are not always reliable correlates either, since there are several pairs of similar small carnivores in which one has delayed implantation and the other has not. For example, the North American river otter, the stoat and the western spotted skunk all have delayed implantation, while their ecological equivalents the European river otter, the common weasel and the eastern spotted skunk do not.

The evolutionary origin and selective advantage of DI have been debated for years (Thom et al. 2004). The remarkably high incidence of this character among the Mustelidae suggests some kind of phylogenetic explanation. On the other hand, the *origin* of such an important feature of reproduction is a separate question from that of its *maintenance* in living animals over evolutionary time. No ancestral character could be so consistently retained among descendant lineages if it

were not associated with a significant adaptive advantage. The great diversity in size, habitat, and life span among mustelids and the great variation in hormonal mechanisms starting and ending the period of delay make any proposed advantage unlikely to apply to all species.

If DI was present in the common ancestor of the Mustelidae, variations in presence/absence or length of DI in descendant species could be accounted for by flexibility in the required endocrinal pathways controlling the mechanism and timing of implantation. Such flexibility is certainly visible in living species which have facultative and/or variable periods of delay, or none at all. Potential explanations for the advantages of DI in living species include the following:

1. Because DI separates the mating and birth seasons by longer than one cycle of gestation, each activity can be undertaken at the most favorable season for mating success and for the survival of offspring (Sandell 1984). It should therefore be an adaptive advantage in short-cycle species living in seasonal environments, allowing young to be born in early spring when food first becomes abundant, without requiring the adults to search for mates in mid-winter – the time when they need all their energy to keep warm. If so, DI should be more common in species living in more severe climates further north, whose young benefit from having a full summer to grow and mature before facing their first winter, and this is generally true.
2. The disadvantage of DI to the adult female is that it lengthens the total gestation period, meaning that a pregnant female must survive for longer before she can birth her pups. Therefore, one would expect DI to be more common in longer-lived (and generally larger) species, and this too is generally true. One conspicuous exception is the small, short-lived stoat, but in that case there could be a special reason (King 1984). The stoat has a unique combination of DI with an extraordinary precocity of the juvenile females: they pass puberty as infants, and are fertilized by an adult male

while they are still blind and unweaned. This surprising capability confers an extra advantage to the young females, balancing the obligate delay against their short lives: virtually all of them are fertilized before they leave the nest (King et al. 2003). It is also a massive benefit to the adult male, who is guaranteed a harem of young mates and huge reproductive success for his genes. (The stoat's similar but independently evolved North American cousin, the long-tailed weasel, also has juvenile precocity but in a less extreme form: the young females are already dispersed and independent by the time they become receptive).

The common weasel is not as closely related to the stoat as it looks, and besides, it is too short-lived for this strategy to work, so it has neither feature. Instead, young weasels born early in a season of exceptional food supplies can produce their first litters at 4 or 5 months of age (Table 1). If combined with high survival rates and second litters by adult females, the density of a weasel population can increase fivefold over a single summer (King and Powell 2007).

3. In species in which the female remains receptive for several days, DI could enable more than one father to contribute to a single litter. Where the two genders live on large and separate home ranges and may encounter each other infrequently, this effect, known as multiple paternity, allows the female to mate with a higher-ranked male even after having been served by a lower-ranked one. Later blastocysts join the earlier ones in delay, and at the right time they all implant together and produce an even-aged litter. This extra degree of mate choice benefits the female's chances of finding the best possible father for her offspring, and incidentally increases their genetic diversity. Alternatively, in sociable species like the European badger, mating activity goes on all year, in part as a guarantee of social acceptance. Delayed implantation at around the time of the winter solstice ensures that all cubs are born at about the same time in spring, mostly to the older, more dominant females (Yamaguchi et al. 2006).

## Conclusion

The various members of the Family Mustelidae are widespread and successful carnivores which have adapted to almost all habitats available around the world, in ways that enable them to avoid competing with rival Carnivores, the felids (cats) and canids (dogs). Instead, they specialize in a great variety of predatory niches all of their own. Their trademark long bodies and short legs are perfect tools for solitary burrowing, climbing, and swimming, and these hunting methods are reflected in their habitat choices and diets, which in turn decide their life histories.

### Synonyms

[Mobility](#); [Motion](#); [Movement](#)

### Definition

Movement of the family of carnivorous mammals that includes weasels, otters, marten, ferrets, badgers, and wolverines.

### Introduction

Members of the family Mustelidae share a similar morphology that involves an elongated body and short legs relative to mammals of similar body mass. This morphology facilitates hunting in unique or under-utilized ecological niches and may be a compromise between the abilities to exploit specialized habitats and to overpower relatively large prey (King and Powell 2007). While the differences in habitat specialization are associated with additional morphological adaptations to maximize success in ecological niches including aquatic, terrestrial, semiarbooreal, and fossorial habitats, it also translates into differences in locomotion among the species. For instance, otters use their elongated body for dorsoventral propulsion through water (Williams 1983a; Williams et al.

2002). American (*Mustela americana*) and Pacific martens (*M. caurina*) and fishers (*Pekania pennanti*) search for prey within subnivean space (spaces located underneath the snow between the snow and the ground) and in tree cavities (Buskirk et al. 1989). Other species including ferrets, weasels, and badgers hunt prey underground in fossorial habitats (Zub et al. 2011). However, there are common challenges for these species related to this body morphology: gaits are influenced by the short legs resulting in elevated stride frequency (Tayler et al. 1982), energetic economy is impacted because of the cost of supporting a long body with short limbs and by other morphological adaptations to exploit a specific habitat, and the higher surface area to volume ratio related to the long body also results in high energy expenditure during locomotion (Williams 1983b). Thus, understanding locomotion in Mustelidae includes consideration of four major variables: ecological niche or habitat, morphology, gait and posture, and energetic economy related to locomotor performance.

### Aquatic Mustelids

Mustelids that occupy aquatic habitats include 13 extant species of otters and 2 species of mink (*Mustela* spp.). These species' lifestyles include semiaquatic, aquatic, freshwater, and marine habitats with some species, like the North American river otter (*Lontra canadensis*), utilizing a range of these. For this group, body morphology strongly influences locomotor performance both in water and on land. All aquatic or semiaquatic mustelids have reduced cervical segments in their vertebral column (compared to other carnivores) to streamline the body (Taylor 1989). Adaptations for aquatic locomotion vary from mink (*Neovison spp.*), which have very few adaptations despite spending considerable time in aquatic habitats, to sea otters (*Enhydra lutris*) that possess many adaptations for a marine environment and rarely visit terrestrial habitats.

In aquatic habitats, the long body and reduced limb length of this group results in a stream-lined shape that reduces body drag, increases speed

during swimming locomotion, and consequently decreases the energetic costs of locomotion (Fish 2000). Otters use dorsoventral propulsion, a wave-like undulatory movement, as an energetically efficient means of locomotion in water. When using undulatory movements, the muscles in the lumbar region of the back provide most of the energetic movements, the forelimbs are held close to the body to reduce drag, and the hind limbs are extended parallel to the tail (Tarasoff 1972). The toes of otters are webbed to increase thrust generation while swimming, although this aquatic adaptation may reduce agility on land (Williams 1983b). Otters also have short forelimbs (Tarasoff 1972) because most of their forward propulsion originates in the lumbar and caudal regions of the body (Taylor 1989). However, mink, a more semiaquatic group of mustelids, do not use dorsoventral propulsion and, instead, swim at the surface of water and propel themselves with leg strokes. Mink are capable of diving and swimming while completely submerged but primarily dive when in pursuit of prey. The toes of mink are only slightly webbed, and they have relatively smaller feet compared to otters. The smaller foot size results in low surface area for forward propulsion while in water but has greater benefits for terrestrial locomotion. In water, mink compensate for their smaller and less effective feet with longer stroke lengths, a higher stroke frequency, and use both fore- and hind paws for propulsion, result in an energetically costly form of aquatic locomotion (Williams 1983a). Sea otters use both surface and submerged swimming and spend the majority of their time in the ocean (Estes 1980). The large size of the hind feet and even shorter hind legs (relative to other mustelids) of sea otters are effective adaptations for aquatic locomotion but decrease terrestrial locomotor performance. Submerged swimming in sea otters is half as energetically expensive as surface swimming at the same speed because of a decrease in form drag achieved through body morphology (Williams 1989). Unlike mink but like river otters, sea otters use dorsoventral undulation of the body and tail for forward propulsion during submerged swimming, and while it may not provide an energetic benefit,

it does increase swimming performance in terms of maneuverability and speed (Williams 1989). Sea otters also use movements originating in the pelvic region and their dorsoventrally flattened tail to move while floating on their back (Tarasoff 1972).

Most otter and mink species also use terrestrial habitats to varying degrees. Sea otters are capable of limited terrestrial locomotion and are the most aquatic species in this family. For some of these species, the flexible, elongated body can reduce locomotion costs on land. However, at lower speeds energy costs are high because of the high stride frequency associated with short legs. At higher speeds, otters and mink experience reduced transport costs through spinal flexion (Williams 1983b; Williams et al. 2002). Spinal flexion accelerates the front half of the elongated body during rebound movement and propels the animal forward like a spring during bounding locomotion, (Williams 1983b, Williams et al. 2002). When using spinal flexion, bound/stride length increases without increasing stride frequency (Williams 1983b). Mink exploit this economy by transitioning to a bounding gait at a lower speed than would be predicted based on body mass to maximize energy economy during locomotion (Williams 1983b).

## Terrestrial Mustelids

Terrestrial mustelid species include the stone or beech marten (*Mustela foinea*), grisson (*Galictis* spp.), and many of the weasels (*Mustela* spp.) Mustelids that spend the majority of their time in terrestrial habitats do not possess specific adaptations for locomotion beyond the general mustelid morphology. Grissons, however, possess webbed toes and will swim and climb trees although they are considered primarily terrestrial (Yensen and Tarifa 2003). Indeed, many primarily terrestrial mustelids also use fossorial, arboreal, and aquatic habitats to some degree.

During terrestrial locomotion, most mustelids skip the trotting gait that involves the opposite front and hind leg moving in unison and suspending the body between alternations of legs

(Hildebrand 1977; Williams 1983b). Instead, weasels and martens are more likely to transition from walking directly to a half-bound gait possibly because of the challenges related to the physical dynamics of a trot with the arched back and short legs of mustelid morphology (Gambaryan 1974; Williams 1983b). During the half-bound, the front feet contact the ground individually followed by the hind feet contacting the ground together. This movement then allows for spinal flexion in some species. This flexible form of locomotion allows weasels and other terrestrial mustelids to increase speed quickly by using muscles to propel the front limbs forward (Hildebrand 1982) and well-developed back and abdominal muscles to forcefully extend, flex, or contract the back during locomotion (Alexander and Jayes 1981). Many mustelids have higher cost of transport at low speeds, with increased energetic economy at higher speeds (Williams et al. 1983b) likely as a result of this spinal flexion. Greater grissons use intermittent locomotion (frequently pausing between movements) (Kaufmann and Kaufmann 1965), while bounding most likely as a predation strategy to pause and search for prey but possibly as a strategy to reduce energetic costs. Because of the general body morphology of mustelids and the related high surface area to volume ratio, these carnivores generally use or lose a large amount of energy even at rest. Therefore, maximizing and reducing energy use by limiting locomotion or exercise is yet another strategy to conserve energy (Chappell et al. 2013).

### Semiarboreal Mustelids

Semiarboreal mustelids include martens, fisher, and tayra (*Eira barbara*). These species use both terrestrial and arboreal habitats while hunting for prey and are skilled at climbing and moving above the ground through trees. Semiarboreal mustelids have been described as pursuit predators that pounce on prey, unlike other arboreal predators including felids that often use sit-and-wait predation and are quite agile at pursuing prey like birds and squirrels through trees. In order to use arboreal habitats, these species possess strong fore-

and hind limbs for climbing quickly, and in some species, the hind feet can be supinated or completely rotated (Powell et al. 2003) to increase control and grip when moving up and down tree trunks. Leaping movements between branches requires rapid and powerful extension of hind legs while using the tail for balance but possibly also as a parachute to increase control over downward movements (Taylor 1989).

Semiarboreal mustelids are also known to move through subnivean spaces in search of prey as well as use terrestrial habitats more generally. During terrestrial locomotion, these semiarboreal species also appear to either skip or minimally use the trot gait. Unlike the aquatic mustelids, these species have less curvature in the spine and either do not use spinal flexion during locomotion or use it very minimally. Pacific marten experience reduced spinal curvature during locomotion at high speeds. This curvature is considerably less pronounced and more posterior than in river otters or mink suggesting minimal benefits from spinal flexion during locomotion (Flaherty et al. 2014). Even without spinal flexion, these species still display greater energetic economy at higher speeds compared to lower speeds. Instead, the shift to a bounding gait reduces stride frequency and likely saves energy through mechanical energy recovery. Similar to locomotion in long-bodied canids, energy saving occurs during the natural rise and fall of the center of gravity of body mass during locomotion (Williams et al. 2002).

### Fossorial Mustelids

Fossorial mustelid species include badgers (*Meles* and *Taxidea* spp.), ferrets (*Mustela* spp.), and polecats (*Vormela peregusna*). The morphological adaptations for fossorial lifestyles in mustelids occur primarily in the feet (Taylor 1989). Badgers use their feet to dig and move soil and have developed large claws, heavily muscled bodies (Hildebrand 1985), and enlarged and strong leg bones to increase stability as well as surface area for attachment of the large muscles, especially shoulder muscles, used in digging (Taylor 1989).

The long claws influence the gait used by fossorial mustelids; the European badger (*Meles meles*) places more pressure on the toes using a digitigrade stance (Yalden 1970), while the American badgers' (*Taxidea taxus*) weight rests on the lateral portions of the paws resulting in a more plantigrade stance and removing weight from the large claws. Both species of badgers are also able to hyperextend their wrists (Taylor 1989). The overall body morphology is relatively short and flat with minimal bending or movement in the wide trunk. In the honey badger (*Melivora capensis*), trunk movement is reduced to the point of little to no lateral bending or sharp turns during locomotion; instead the honey badger rears on its hind legs to rotate the trunk perpendicular to the ground and returns to a four-legged stance oriented in a new horizontal direction (Eilam 1994).

Badgers use ambulatory locomotion and rarely use faster gaits. While the European badger has been observed running using a gait that involves overlap of hind feet and fore feet (Neal 1948), it is unlikely that the American badger uses a fast gait and relies primarily on a variable speed walk when searching for food. The large mustelids, like American badgers and honey badgers, likely do not use the half-bound or bounding gait because of a more rigid spinal column (Dagg 1973) and wider trunk. Faster gaits in these larger mustelids may not be necessary for pursuing fossorial prey. However, locomotion in badgers is relatively unstudied and little is known about the use of faster gaits in these species.

Ferrets and polecats are smaller-bodied than the badgers. These species use similar gait patterns when walking in a tunnel and when walking above ground despite the reduced body profile, and differences in pelvic height and limb extension in the two habitats (Horner and Biknevicius 2010). The crouched position during fossorial locomotion likely leads to increased energetic demands in response to the metabolic cost of maintaining this posture. While in tunnels, ferrets only use symmetrical gaits (walking, trotting, running) and no asymmetrical gaits (bounding, semi-bounding). The low ceiling and the crouched position likely limits movement of spine and

body axis, eliminating the opportunity to employ spinal flexion and other movements observed during half-bounds and gallops (Horner and Biknevicius 2010).

## Conclusions

Mustelid locomotion, both in terms of gait and energy economy, is heavily influenced by body morphology, which reflects adaptations to optimize habitat use and exploit unique ecological niches. As a result, there is considerable variation in the forms of locomotion used by members of this mammalian family.

Some mustelids cannot easily be classified into one of the four groups described above and have morphological adaptations for exploiting aspects of >1 habitat. For example, the Chinese ferret-badger (*Melogale moschata*) has webbed digits, long and robust claws, and while primarily terrestrial, occupy burrow systems and will use arboreal habitats (Storz and Wozencraft 1999), clearly suggesting additional unique locomotor abilities. Currently, only research on minks has investigated how adaptations for using multiple habitats may impact locomotion (Williams 1983a, b).

Locomotion is still relatively unstudied in this diverse carnivore family. Because mustelids and other carnivores disperse long distances and are capable of sustained locomotion, understanding this aspect of natural history and animal biology has important implications for conservation and wildlife management.

## Mustelidae Morphology

Anna Loy  
 Envix Lab – Department Biosciences and  
 Territory, University of Molise, Pesche, Italy

## Introduction

Despite recent molecular data evidenced that skunks do not lie within the mustelid group (Sato et al. 2012), Mustelidae, bearing 56 species in 22 genera, are the largest and oldest family in

the order Carnivora (Nyakatura and Bininda-Emonds 2012). The family originated in Eurasia in the middle-late Miocene and underwent a rapid evolution and diversification, resulting in a remarkable ecomorphological diversity (Koepfli et al. 2008). Koepfli et al. (2008) identified two major clades, Lutrinae and Mustelinae, and eight minor clades of Mustelidae. American and honey badgers (genera *Taxidea* and *Mellivora*) are monotypic lineages basal to all other mustelids. The clade Martinae, including taira, wolverine, hog badger, Eurasian badgers (genus *Meles*), and martens (genus *Martes*), is in turn basal to the clades Helictinae (ferret badgers), Galictinae (spotted and striped aposematic species: grisons, zorillas, the marbled polecat, and the African striped weasel), Mustelinae (minks and true weasels), and its sister clade Lutrinae (otters).

## Coat

Mustelids have a dense and rich underfur, and overharvesting for pelt trade led many species to the brink of extinction in the last century. Ermines, sables, martens, fishers, otters, and minks were among most harvested species, while hairs of badgers have been long used as paint brushes (Domingo-Roura et al. 2006). The trapped air in the underfur helps both to retain body heat and to maintain a stable body temperature. Aquatic and semiaquatic mustelids like otters and minks have the densest underhairs, i.e., highest number of underhairs per bundle, which facilitates the hair interlocking and increases the efficiency of the insulating air barrier during prolonged submergence in cold waters (Liwanag et al. 2012). The fur of the sea otter *Enhydra lutris* is the thickest among mammals, with up over 1,000,000 hairs per square inch. According to Liwanag et al. (2012), the ancestral form of mammal insulation depending on the external fur became the primary thermal barrier in water in aquatic and semiaquatic mustelids, while in other marine carnivore lineages (Pinnipeds) primary insulation relies on internal blubber layer (Liwanag et al. 2012). Insulation in otters is also promoted by geometric scale patterning of the underhairs, which favors interlock of hairs (Fig. 1).

Despite a dense underfur functions as a good insulator, insulating value is diminished by water vapor, water penetration of the fur, and the altered position of the fur relative to the body during swimming and diving (Kuhn and Meyer 2009, 2010). To overcome these drawbacks, guard hairs of aquatic and semi-aquatic mustelids are flattened so that the air layer trapped by the underfur is maintained also during swimming. Flattening of guard hair is especially efficient in sea otters, as this species lacks arrector pili muscles (Liwanag et al. 2012). Flat and elongated scale patterning on the guard hairs is found in otters and ermines and is likely an exaptation of mustelids hairs (Liwanag et al. 2012). Specialized oil glands further increase insulation by waterproofing of the hair. The three layers of the mammalian hair, i.e., cuticula, cortex, and medulla, can be used for species identification (Teerink 1991). However, Toth (2002) has shown that only combinations of hair traits allow a reliable identification of species.

Mustelid pelage is generally uniform in color, with exception of the clade Galictinae, including species with spotted and striped aposematic pelage (genera *Vormela*, *Poecilogale*, and *Ictonyx*). At high altitudes or latitudes where snow cover is common in wintertime, the ermine *Mustela erminea*, the long tailed weasel *M. frenata*, and the least weasel *M. nivalis* undergo a complete change of their coats from brown to white (“ermine” morph). In the Japanese weasel (*Mustela itatsi*), the pale yellowish winter pelage turns to dark brown in summer.

The black tail tip shown by ermine and long-tailed weasel in winter is likely useful to focus the attention of potential predators away from the body.

Facial and throat markings occur in many species, like polecats, martens, badgers, and giant otter, and are often used in field studies for individual recognition (see for example Groenendijk et al. 2014; Fig. 2).

## Body Shape and Postcranial Skeleton

In spite of little variation in body shape, i.e., small head, long neck, and body, Mustelids are highly

**Mustelidae Morphology, Fig. 1** Scanning electron micrographs showing the cuticular scale patterns of dorsal guard hairs (top) and dorsal underhairs (bottom) of a sea otter *Enhydra lutris*, a North American river otter *Lontra*

variable in size, from 30 cm and 24 gr of a least weasel (*Mustela nivalis*) – the world’s smallest carnivore – to 130 cm and 45 kg of a sea otter (*Enhydra lutris*) (Fig. 3).

However, most members of the family show a similar size, a phenomenon that according to Meiri et al. (2007) can be explained by similar prey selection rather than by competition.

Mustelids are skilled hunters, exploiting a great diversity of both vertebrate and invertebrate prey (King et al. 2010). They often hunt in burrows and crevices, and some species chase their preys on trees (e.g., marten) or in water (e.g., sea otters, minks). The short-legged, long and flexible body and tail of most species are considered ancestral traits of the family, evolved to run after and chase rodents in burrows, whereas the squat shape with short tail of badgers and wolverine is believed considered a derived trait (Ercoli and Youlatos 2016; Fig. 4).

In accordance, Koepfli et al. (2008) suggested the main driver of mustelid radiation was the spread of fossorial preys that followed the replacement of forests with open environments, as a consequent of aridity turnover of the global climate during the middle-late Miocene.

Limbs of Mustelids have five digits each, usually provided with strong curved and nonretractile claws that are often shown in prints (Halfpenny

and Biesiot 1986). Most members of the family are digitigrade although few are plantigrade (Fig. 5). Some species like otters are normally plantigrade but can be digitigrade when running (Halfpenny and Biesiot 1986). In most otters, minks, and two South American weasels, the digits are webbed to facilitate swimming.

The family shows a wide range of locomotory adaptations, including ground dwelling (weasels and wolverine), arboreal (martens and ferret), fossorial (badgers and black footed ferret), as well as aquatic and semiaquatic (sea and marine otters, freshwater otters, minks) species. Whereas gravity and inertial forces are the principal constraints on locomotion in terrestrial species, drag forces are dominant in water (Fabre et al. 2015).

To reach relative high-speeds during running with their short limbs, Mustelids adopt a bounding locomotion, in which jumping is performed by an extended axial phase synchronized with limb movements (Ercoli and Youlatos 2016). The high

speed runs of the wolverine and the undulating swimming of otters are taught to be derived from such ancestral traits. Moreover, in semi-aquatic animals, drag is minimized by streamlining body shape and appendages.

Limbs adaptation and convergence in long bone morphology in mustelids were recently investigated by Ercoli and Youlatos (2016) and by Botton-Divet et al. (2017). According to Ercoli and Youlatos (2016), the forelimb of most Mustelids shares a well-developed epicondyle and supinator crest of the ulna, this latter oriented in the proximodistal direction and flaring laterally. In the majority of scansorial and arboreal species, the scapula has an ample acromion process that tilts cranially with respect to the spine, the humeral head is located more proximally than the lateral and medial tuberosities, and the radial head is elliptical to rounded. In scansorial species, the olecranon process of the ulna is moderately to poorly developed. In most arboreal species, including the tayra, characterized by a mosaic of autopodial specializations to arboreal locomotion and less modified ancestral proximal elements, the anterior surface of the distal ulna bears a distinct pronator

crest (Ercoli and Youlatos 2016). In terrestrial species and in the scansorial boulder *Martes*, the acromion process of the scapula is reduced and/or with a lesser tilt. As to the hind limbs, the femoral head of terrestrial species possess more abrupt limits and a more medial position in respect to the major axis of the diaphysis. In scansorial and arboreal species is slightly more elevated or similar in height in respect to the major trochanter. The calcaneum has a well-developed trochlear process, and the metatarsals are long in relation to the rest of the hind foot. The pelvis of both scansorial and terrestrial musteloids possesses a relatively long ischium. High specialization of mustelids limbs is found in fossorial badgers and aquatic otters. In the fossorial *Meles* sp., the forefeet are provided with strong claws that enable to dig complex tunnels systems, the scapula has a prominent ridge acromion process, the deltoid ridge is prominent, and like in scansorial species, the supinator crest is relatively well developed in the proximodistal direction while the medial epicondyle is well developed (Ercoli and Youlatos 2016).

Otters and the two minks (*Mustela lutreola* and *Neovison vison*) represent three independent

returns to the aquatic environment among the Musteloidea (Sato et al. 2012). Adaptations to water followed different pathways and reached different efficiency in Mustelinae (minks) and Lutrinae (otters) (Botton-Divet et al. 2017). Minks retain the four limb terrestrial locomotor patterns of the Mustelinae, swimming by a drag-based propulsion with paddling appendages, whereas otters use a more efficient lift-based propulsion with oscillating hydrofoils. Also, otters show various swimming gaits depending on the species (Botton-Divet et al. 2017), and their limbs display more robust bones than Mustelinae (Fabre et al. 2015). This latter trait was interpreted as an adaptation to both support body weight during terrestrial locomotion and to stabilize the body during swimming (Nakajima and Endo 2013). Lutrinae shows a large diversity in all bones but the humerus, likely as a consequence of diversity in swimming gaits (Botton-Divet et al. 2017). The sea otter shows the most derivative traits, as it extensively uses its forepaws to manipulate objects, and not for aquatic locomotion. Also, it seldom walks on land, and has lost the ability to run (Botton-Divet et al. 2017). The peculiar feeding behavior of the sea otters, using forepaws to dig, gather, hold, and often manipulate prey with tools, is testified by its unique radial and ulnar shape, which are slender and with a shorter and straighter olecranon process compared to that of other mustelids (Botton-Divet et al. 2017). In contrast, minks display a high degree of convergence in the shape of their long bones, likely as the result of same functional pressures on the forelimb. Convergence is especially significant in the humerus. This bone is characterized by an expansion of the cranial part of the diaphysis, a wide area between the greater trochanter and distally expanded deltoid crests leading to greater insertion areas of the shoulder flexor, the abductors, and the retractor muscles (*m. deltoideus*, *m. pectoralis major*, and *m. pectoralis minor*) (Ercoli et al. 2015; Botton-Divet et al. 2017). However, despite their similar shape, the forelimbs of the two minks differ in some traits. The shape of the long bones in European minks *Mustela lutreola* is closer to that of Lutrinae. They show an antero-distal displacement of the

shoulder retractors implying an extended in-lever and therefore a more powerful retraction of the shoulder, likely related to the mechanical requirements of padding when moving in a denser medium (Botton-Divet et al. 2017). Also, European minks have a wide epicondylar crest reminding that of otters, even if less developed. This crest provides origin for the *m. anconeus*, which assists elbow extension on the caudal side, and is also the origin for several digital and carpal extensors and the wrist flexor on its laterocranial side (Botton-Divet et al. 2017). American mink *Neovison vison* has a longer olecranon process of the ulna compared to its terrestrial relatives, providing a longer in-lever for the elbow extensor. This trait seems to be linked with body mass, suggesting a role for sustaining larger mechanical load during terrestrial locomotion (Botton-Divet et al. 2017). The American mink tends to converge with the Lutrinae for the shape of the ulna, femur, and tibia, in accordance with the larger size of this species. Ercoli et al. (2015) recognized some muscular traits of the limbs shared by all mustelids, such as the presence of *rhomboideus profundus*, an angular head of *triceps brachii*, and, apparently, the absence of a *flexor digitorum brevis manus*. The lesser grison *Galictis cuja* possesses an unexpected *articularis humeri* and lacks the *tensor fascia antebrachii* (Ercoli et al. 2015). Also, according to Ercoli et al. (2015), *Ichthyonychia* and *Mustelinae* possess traits related to a high resistance in landing during bounds and to the increase of gait length during epigeal and subterranean crouched. These traits include a strong and subdivided protractors, a sagittal rotators of the forelimbs, and shoulder and elbow extensors. Powerful neck musculature assists during hunting and carrying of prey. Ercoli et al. (2015) found that the configuration of the *rhomboideus* and the absence of *coracobrachialis* are diagnostic of subfamilies.

## Skull Morphology

As for most vertebrates, the skull of mustelids is a highly informative structure, retaining both phylogenetic and adaptive signals (Hanken and Hall

1993). Adaptive significance is linked to the deep involvement in many critical functions, such as the protection of the brain and the special sensory organs, food acquisition and manipulation, as well as breathing and communication skills (Hanken and Hall 1993). Recently Dumont et al. (2016) also highlighted differences in skull traits of the Musteloida related to locomotor adaptations, such as the orientation of orbit, cranial base, and occipital condyles. Mustelids share with ursids, canids, viverrids, and herpestids an “arctoid” skull design, whereas a “feloid” skull is characteristic of felids, hyaenids, and some viverrids. The typical “arctoid” skull has a large head and long snout housing large cheek teeth suitable to exploit a variety of feeding resources, including vegetables (Van Valkenburg 1988). Mustelids skull partially deviate from the arctoid skull in that it has generally a long braincase (Fig. 6).

Trophic adaptation is a main driver of skull morphological changes in Mustelids skull, and evolutionary response to feeding pressure can be very rapid, even at subspecific level (Timm-Davis et al. 2015). Also, the high degree of morphological divergence observed in strictly related species suggests feeding adaptive pressures and intraguild competition having a more relevant role in shaping skull morphology of Mustelids than phylogenetic constraints (Abramov et al. 2016). As an example Abramov et al. (2016) suggested resource partitioning and reduction of ecological niches’ overlap as main factors explaining the differences in skull morphology between the sympatric and closely related polecats *M. putorius* and *M. eversmannii*. Also, a different degree of

hypercarnivory was claimed to explain the differences in the skull design of the closely related *Martes martes* and *M. foina*, with selective forces acting to either increase the bite force at the expense of gape or vice versa (Loy et al. 2004). Finally, Timm-Davis et al. (2015) found significant differences in the skull shape of Lutrinae, also within foraging types.

Thus, we can affirm that the shape of the mustelid skull markedly reflects their diets.

Mustelids should consume a large amount of food to maintain their basal metabolism; as a consequence, animal prey is a major component of their diet (King et al. 2010). Only few species include vegetables in their diet: badgers (genera *Taxidea*, *Arctonyx*, *Mellivora*, and *Meles*), pine marten *Martes foina*, beach marten *M. martes*, and tayra *Eira Barbara*. The European badger also relies heavily on earthworms, which can make up nearly two-thirds of its diet (Roper 1994). Some mustelids, such as wolverines and fishers, may also feed on carcasses of animals killed by other predators (Landa et al. 1997; Zielinski et al. 1999).

Timm-Davis et al. (2015) provided an extensive and accurate analysis of the morphology and functional performances of otters’ skull in relation to feeding adaptations. Otters have evolved two feeding specializations. Mouth-oriented piscivores use raptorial biting to capture elusive prey in open water, while hand-oriented otters chase nonelusive, benthic organisms (e.g., crustaceans, mollusks) which armors require high crushing capabilities. Mouth oriented habit is considered the basal feeding mode of otters (Berta

**Mustelidae Morphology, Fig. 6** Comparison of the typical “arctoid” skull of a brown bear (left, *Ursus arctos*, 3d scanning, Coll.N. C60 National Park of Abruzzo, Lazio and Molise, courtesy Centro Radiologico Potito,

Campobasso, Italy) and that of an Eurasian otter (right, Swedish Museum of Natural History Coll.N. NRM-20115598, 3D photogrammetric reconstructions by A. Loy). © Anna Loy

and Morgan 1986), and it is typical of North American river otter (*Lontra canadensis*), neotropical river otter (*Lontra longicaudis*), giant river otter (*Pteronura brasiliensis*), smooth coated otter (*Lutrogale perspicillata*), Eurasian river otter (*Lutra lutra*), spotted-necked otter (*Hydrictis maculicollis*), and hairy-nosed otters (*Lutra sumatrana*). Hand-oriented predators include the sea otter (*Enhydra lutris*), the African clawless otter (*Aonyx capensis*), the Congo clawless otter (*Aonyx congicus*), the Asian small-clawed otters (*Aonyx cinerea*), the marine otter (*Lontra felina*), and the Southern river otter (*Lontra provocax*) (Medina-Vogel et al. 2004; Medina-Vogel and Gonzalez-Lagos 2008; Timm-Davis et al. 2015). These specializations have profound influence on skull morphology, as jaw motion velocity (required in mouth-oriented species) and biting capabilities (required in hand-oriented species) cannot be simultaneously maximized (Timm-Davis et al. 2015). Thus, jaws are designed to either increase velocity at the expense of biting capability. In mouth-oriented predators, longer, narrower skulls and long mandibles position the resulting bite force farther from the temporo mandibular joint, providing jaws with greater velocity at the expense of bite force

capability. Hand-oriented predators have shorter skulls and mandibles providing a high bite force and further modified dentition (e.g., wide, flat occlusal surfaces) (Timm-Davis et al. 2015). Extreme skull morphologies are shown by the mouth-oriented giant otter and the hand-oriented sea otter, having blunt mandible and concomitantly wide skull (Fig. 7).

Mouth-feeding river otters have hypertrophied jaw muscles even compared to terrestrial mustelids. The temporalis muscle and the zygomatico-mandibularis muscle are responsible for exerting the main force when jaws are fully open, while enlarged digastric muscles allow the rapid jaw motion necessary for catching elusive fish underwater (Timm-Davis et al. 2015). These characteristics are reflected in the skull, having broad mastoid processes where the digastric muscles originate. Rapid motion of the jaws is especially favored in the giant otter that has the longest skull and mandibles and the smallest temporalis and masseteric mechanical advantages among otters, and a bite point (at all bite locations; e.g., canines, molars) positioned farther from the temporal-mandibular joint (Timm-Davis et al. 2015). Conversely, the skull of sea otters is deeply shaped by durophagy, possessing taller and wider

**Mustelidae Morphology, Fig. 7** Left: ventral view of the skull of a sea otter *Enhydra lutris*, deeply shaped by durophagy and hand oriented feeding (Museum National d'Histoire Naturelle de Paris, coll. N. MNHN-ZM-MO

mandibular rami, and shorter, blunter skulls than other otters (Fig. 7). Great width of both braincase and rostrum, great interorbital distance and the corresponding differences in jaw adductors likely explain the increased zygomatic length.

The great masseteric mechanical advantage, the height of the mandibular ramus, and depth of the mandibular fossa relate to increased bite force, while a greater moment arm of the masseter also generates more control over mastication (Timm-Davis et al. 2015). Sea otter mandibles have relatively tall and vertically oriented rami combined with a long zygomatic arch for masseter attachment. A long zygomatic length allows muscles to attach more anteriorly, thus improving bite force while allowing a larger gape (Timm-Davis et al. 2015). Otter adductor muscle architecture and physiology are modified to allow for a wide gape while maintaining a high bite force. Sea otters also possess a higher rostrum, offering an increased area for muscle attachment. Shorter and wider skulls increase the bite force and bring the canines closer to the fulcrum, which increases the mechanical advantage of the masseter even at the tip of the jaw, resulting in increased bite force at this position as well.

North American, Neotropical, and Eurasian river otters, smooth coated otter, spotted-necked otter, and hairy-nosed otters primarily feed on fish, but also incorporate crustaceans, amphibians, birds, and mollusks in their diet. Their skull shape is thus expected to be intermediate between the

strictly piscivorous giant otter and hand-oriented invertebrate specialists (Fig. 8).

Timm-Davis et al. (2015) showed that in the North American river otter the relatively long mandibles and higher temporalis and lower masseteric mechanical advantage position bite force at the anterior mandible at the canines, which favors a mouth-oriented predator that also may consume large fast moving fish like salmonids.

Similarly, the Asian small-clawed otter *Aonyx cinereus* is a hand-oriented predator that consumes a broader spectrum of prey than sea otters. In this species, the mechanical advantage of temporalis, which large mass is witnessed by a long zygomatic fossa, is significantly greater than the masseter's, suggesting increased force at the anterior jaws near the canines, allowing to catch fast prey by this hand-oriented feeder.

Timm-Davis et al. (2015) suggest that trophic differentiation in otters may be either deeply or shallowly rooted in phylogeny, and is at least partly replicable.

The transverse condyle of the mandible is locked into the postglenoid process partially enclosing the glenoid fossa, so that in some species the condyle of the dentary bone is difficult to disengage from the fossa (Van Valkenburg 1988). This enables the animal to maintain it firmly hold, but limits jaw movements. Other cranial features of Mustelids are the absence of alisphenoid canal, a single-chambered auditory bulla, and a supra-meatal fossa in the middle ear (Wolsan 1993).

Teeth

The mainly carnivorous diet of Mustelids is reflected in their teeth: canines and molars are large and sharp, while incisors are usually small. The dental formula is quite variable, from I3/3, C1/1, P4/4/, M1/2 = 38 to I3/3, C1/1, PM3/3, M0/0 = 28 (Table 1).

Mustelids that crush their prey or feed on vegetable though food possess broad flat occlusal surface areas of the cheek teeth (Timm-Davis et al. 2015). These include wolverines, fishers, badgers, and sea otters, these latter showing the largest relative occlusal surface areas among mustelids, and the only possessing bunodont dentition (Fig. 9).

Specifically, the carnassials (P4 and m1) are either trenchant or modified into crushing teeth. In the sea otter and other otter species specialized to feed on hard shelled mollusks (*Aonyx congicus*, *Aonyx cinerea*, *Lontra felina*, and *Lontra provocax*) have carnassials with rounded cusps adapted to crushing and broad postcarnassials (M1 and m2).

MNHN-ZM-MO 1962-2678) and an Eurasian badger (right, Museum National d’Histoire Naturelle de Paris, coll. N. MNHN-ZM-MO 1998-1247). (© Anna Loy)

Sexual Dimorphism

The evolution of sexual dimorphism in body size and morphology of animals has been related to sexual selection, intersexual food competition, and differential investment in parental care (Hedrick and Temeles 1989). Therefore, sexual

dimorphism is the result of evolutionary changes and constraints posed on each of the sexes independently (Fairbairn 1997).

As in most Carnivora, sexual dimorphism in Mustelid is mainly sexual size dimorphism (SSD), with males larger than females. As an example, in sea otters males are 34% heavier and 8% longer than females. SSD has been explained either by a strategy to avoid intraspecific competition (males and females adapted to catch different preys) or related to polygynous mating system, where small females are favored because they need less energy for daily maintenance and can channel more energy into reproduction, while male's larger size is favored by sexual selection and ability to exploit a wider range of prey (Moors 1980). Loy et al. (2004), by adopting a geometric morphometric approach that allows to disentangle the variation in shape versus variation in size, found significant differences in both the size and the shape of the skull of males and females of the

closely related pine marten *Martes martes* and beech marten *M. foina*. Shape differences were similar, although more marked in the stone marten, with males bearing a larger and shorter skull, larger carnassial teeth PM3 and M1, and more marked postorbital constriction than females (Loy et al. 2004; Fig. 10).

Interestingly, a more marked postorbital constriction in males was also described by Lynch et al. (1996) for the Eurasian otter *Lutra lutra*, while Dayan et al. (1989) found sexual dimorphism in the canine size of three species of weasels from North America.

Sexual size dimorphism of mustelids has been interpreted either as a mechanism to reduce intersexual competition for food by enabling each sex to exploit different prey (Loy et al. 2004) or as a consequence of sexual selection that in polygynous mustelids favors larger males (Moors 1980). As an example, Loy et al. (2004) suggested that sexual dimorphic traits probably

**Mustelidae Morphology, Fig. 10** Dorsal view (left) and palate (right) of a male (top) and a female (bottom) stone marten *Martes foina*. The female skull is smaller and more elongated than that of males and has a wider

postorbital constriction. Also, the palate of females is more elongated than in males, likely due to a different orientation of PM2 and PM3, and to the smaller carnassial PM3 and M1 teeth. © Anna Loy

act on *M. foina* and *M. martes* as a mechanism to avoid both intraspecific competition between sexes and interspecific competition between these ecologically overlapping species. Wiig (1986) found that SSD in skulls of otters, minks, and badgers is also functionally related to the jaw mechanism, as larger males have larger jaw muscles and larger absolute gape. Berdnikovs (2005) found sexual dimorphism in body mass within mustelids to be a consequence of unequal rates of male and female body size evolution, with male body mass being less constrained in its evolution than female mass. In contrast, Gliwicz (1988) suggested extreme body size dimorphism in small mustelids has been constrained by the diameter of the borrows of their common preys. Despite SSD is widespread in Mustelids, there are some exception. Rozhnov and Abramov (2006) found a low dimorphism in cranial characters of *Vormela peregusna* compared with other similar sized mustelids, likely related to low intraspecific competition in habitat and food selection.

## Definition

Causes for and mechanisms by which mustelids move from one location to another.

## Introduction

Navigation, or the process by which an organism moves from one place to another, is a critical behavior for the success of most vertebrates. Organisms accomplish such movements by adapting to cues produced either externally in the environment or internally through physiological or neurological processes. Navigation can be as simple as an individual moving toward or away from a stimulus, or cue. More advanced behavior may include following an established route through one's territory. In its most complex form, animals construct a cognitive map, or a spatial representation of the landscape, which provides the ability to navigate using potentially novel routes based on the locations of positions or landmarks stored in memory (Tsoar et al. 2011; Wiener et al. 2011). Much is known about how some groups of animals use these various techniques to navigate their environment (e.g., birds, insects), but less is known about the mechanisms used by mammals (Gould and Gould 2012).

Members of Mustelidae make up the most diverse family in the Order Carnivora. They can be divided into two primary subfamilies: Lutrinae (otters) and Mustelinae (all other members of the family). Located on five continents and at nearly all latitudes, the adaptive radiation of Mustelidae resulted in the occupancy of a wide diversity of ecoregions and habitat types from oceans and rivers to tropical forests and arctic tundra (Koepfli et al. 2008). Mustelid evolution has thus resulted in an assortment of ecological lifestyles, including aquatic, fossorial, arboreal, and terrestrial. Not surprisingly, they have also evolved a diversity of methods by which they navigate these environments. The application of these methods provides unique benefits while incurring costs related to life history actions such as territory maintenance, prey location, conspecific identification, and juvenile dispersal.

## Sensory Modality of Navigation

Despite their phylogenetic diversity, many species use common techniques and sensory systems to

navigate their environment. For example, olfaction is important for navigation throughout the family. All mustelids possess anal scent glands and many have additional glands on the feet, torso, and elsewhere that produce odiferous chemical secretions unique to each species and often unique to the individual (Brinck et al. 1983; Thom and Hurst 2004). These secretions, usually in combination with other types of scent-marks, are deposited throughout an individual's home range (i.e., area of regular use) on a regular basis. Purposes of the scent-marking behavior vary across species, but the recognition of these glandular secretions via olfaction is an important tool utilized by mustelids to navigate landscapes. For example, individuals may navigate toward scent marks that signal resource abundance and away from scent marks that signal the territory of a conspecific. Olfactory signals such as those produced by scent-marking behavior provide a number of advantages over other methods such as visual or auditory signals. Olfactory signals can be effective in situations or habitats where visual or auditory contact is not possible and can provide a record through space and time of an individual's movements or behavior. Perhaps most importantly, these signals are capable of persisting long after the individual that produced the signal has left the area (Gorman 1990).

Latrine establishment and subsequent use is a specialized form of scent-marking that is common among many of the mustelids. A latrine is a location on the landscape where one or more individuals regularly returns to urinate, defecate, and/or scent-mark. The spatial distribution of latrines varies by species and habitat type, but latrines are most often established strategically to perform functions such as establishing territoriality, signaling resource availability, or promoting sociality. Latrines therefore provide long-lasting cues that can serve as navigational landmarks for individuals in search of resources, a home range, or a mate (Gorman 1990).

In addition to olfaction, mustelids generally possess excellent hearing (i.e., audition) but weaker visual acuity, though all three senses may be used for navigation (Gillingham 1986). Vision tends to be more helpful in navigation at

close distances or for identifying moving objects, while hearing is used for both social and ecological purposes across greater distances. For the more fossorial and aquatic species, tactile senses accessed through vibrissae or forelimbs are also important for navigation. These senses tend to be less relevant to long-distance navigation through the environment, however, and more relevant to close-range processes such as prey capture.

## Territoriality

A key feature of mustelid navigation is the ability to maintain a territory and defend it from conspecifics who would exploit its available resources. A territory is an area defended by an occupying individual or group of individuals. A common strategy is for solitary individuals to maintain territories between members of the same sex, but overlap between members of the opposite sex (Powell 1979). Often a single male's territory will encompass multiple female territories. Thus, individuals must be able to navigate and defend their own territory while avoiding intrusion onto the territories of their neighbors. Other factors such as the sex of the occupant and their relative position in a dominance hierarchy may factor in to territorial movements as well. This generic social pattern may be flexible within species and may be dependent on factors such as resource distribution and availability (Powell 1994). Other social patterns also exist. Some species or populations live in intersexual social groups (e.g., *Pteronura brasiliensis*, *Meles meles* in the UK), others may exhibit territoriality in only one sex (e.g., *Enhydra lutris*), and still others may consist of solitary males and small family groups composed of an adult female and her young (e.g., *Lontra canadensis*). Despite the diversity of social structures, all species likely display some form of territoriality.

Resident and dispersing mustelids use established territorial systems to navigate their environment while mutually avoiding direct encounters. Territoriality in the mustelids is most commonly maintained through scent-marking behavior. Scent marks can be from one or more

of glandular secretions, feces, or urine. For conspecifics, compounds in these scent marks can be complex enough to signal the individual identification of the depositor along with its sex, age, and reproductive status (Brinck et al. 1983; Service 1997). Scent marks are commonly distributed along the edges of territories and at the core of the home range (Hutchings and White 2000), and individuals will follow regular routes to maintain scent marks. These marks are often placed on prominent objects on the landscape such as rocks, trees, logs, or mounds, thereby maximizing exposure to the olfactory signal. Thus when a neighboring or dispersing individual approaches a scent mark, they can readily identify the sex, dominance status, or individual identity of the owner of the mark. Producing scent marks and defending a territory are energetically costly, but potentially less costly than a physical encounter (Gosling and Roberts 2001). When individuals do come in close proximity, visual signals such as facial expressions and body posture, and auditory signals in the form of aggressive vocalizations serve as navigational cues for the intruding individual to avoid the territory of the owner and prevent a physical confrontation. For many species, particularly the Lutrinae, movements and territories tend to follow linear water features on the landscape. This unique pattern of movement may yield higher encounter rates with conspecifics and therefore lead to increased competition and territorial behavior (Quaglietta et al. 2013).

## Foraging

Mustelids are highly active foragers, continually navigating to locate their next prey item. This is partly due to their elongate body shape, which is advantageous for living and foraging in tight spaces or for swimming, but yields a high surface area to volume ratio relative to other mammals in the order Carnivora (Brown and Lasiewski 1972). This pattern of morphology results in rapid loss of body heat and corresponding high rates of metabolism. Thus mustelids must navigate to, capture, and consume a large proportion of their body mass each day to maintain consistent weight. This need

is met by frequent, active bouts of foraging for prey items, driving the need for advanced navigational capabilities. For most of the Mustelinae, primary prey items consist of mobile prey such as small vertebrates or invertebrates including rodents, lagomorphs, birds, amphibians, reptiles, insects, and earthworms. For the Lutrinae, prey are almost exclusively aquatic and can include fish, crayfish, crabs, eels, mussels, insects, sea urchins, and any other aquatic or semiaquatic animal small enough to be handled by an otter. A minority of species are omnivorous or seasonally omnivorous (e.g., *Martes americana*, *Eira barbara*, *Melogale moschata*), but the general rule is carnivory. Navigational processes during foraging therefore vary throughout the family for the detection, pursuit, and capture of prey.

Mustelids do not forage randomly, but in selected directions and locations (Powell 2005). While foraging, the Mustelinae will navigate their home range following a general route or direction that may be used multiple times per day. Along with this route-following behavior, fine-scale foraging movements may consist of short zig-zag motions characterized by high sinuosity where individuals frequently cross their own path checking every cavity, burrow, tree, or other location that may potentially contain prey. During this search phase, the primary senses involved in detecting and navigating toward prey items are hearing and olfaction, especially when prey items are hidden from sight. Vision is generally not acute enough to detect stationary prey items and may not be useful for navigation until prey is in close range. Some species (e.g., *Poecilogale albinucha*, *Mellivora capensis*) will forage with their nose close to the ground, often rooting through debris as they navigate their territory. Another common behavior is to pause frequently and sit back or stand on the hind legs while surveying for signs of predators or prey. Upon detection of a prey item, a chase and attempted capture ensues. Mustelids rarely ambush or stalk their prey, preferring to rush the prey item and quickly end the encounter with a lethal bite to the back of the skull or neck. For the Lutrinae, foraging takes place at relatively stationary locations as opposed to constant traveling, and navigation is required to

move between feeding locations. The process of capturing prey is similar to that of the terrestrial mustelids, except that prey are detected primarily by vision or tactile senses using facial vibrissae that are sensitive to perturbations in the water. The latter sense is especially useful when foraging at night or in murky water. Several species of otters also have highly adapted forelimbs for tactile sensitivity that aid in searching for and handling prey in aquatic substrate (Radinsky 1968). In addition to navigating their environment spatially, navigation of the temporal environment (i.e., choosing when to forage) is also required. Daily activity patterns often align closely with activity patterns of prey items, and such patterns may vary seasonally as well.

Mustelids are capable of maintaining a spatial network (i.e., a cognitive map) of suitable foraging locations for navigating within their home range (Powell 2005). Memory therefore plays an important role in navigation while moving between sites within the cognitive map. For the terrestrial mustelids, such sites are revisited regularly and often lie along established routes followed by the individual throughout the home range. These routes may connect multiple foraging sites, burrows, or otherwise protected locations that can be used for resting between bouts of foraging. For smaller species, overhead cover (e.g., forest canopy, woody debris) is an important component of established routes and may guide navigation, possibly because it reduces risk of predation by aerial predators. Travel through open clearings is rare for such species. Mustelids commonly kill more than they are capable of eating and some may cache their prey along routes or near rest sites. This behavior requires the ability to both remember and navigate to the location of the cache in the future. In addition to route-following, latrines or other scent marks may be used to identify and mark foraging locations. Latrine behavior is more common among the Lutrinae than the Mustelinae, and evidence suggests that otters may use latrines both to signal areas of high resource availability (Prenda and Granado-Lorencio 1996), and to signal locations where resources have been recently exploited (Kruuk 1992). For coastal otters in the UK, these

sites serve to identify locations of freshwater pools important for drinking water (Gorman 1990). In terms of navigation, latrines serve as navigational landmarks that contribute to the cognitive map used by otters and other species to navigate their environment.

## Mate-Finding

As most Mustelids, males in particular, are solitary throughout most of the year, the ability to navigate to the locations of females becomes crucial for reproductive success. For species that occur at higher latitudes, breeding takes place once per year, usually during spring and/or early summer. As one moves toward the tropics, species tend to be more plastic in their breeding schedule and may mate at any time during the year. During breeding periods, territorial boundaries may dissolve as males begin to search both within and beyond their home range for receptive females (Johnson et al. 2000). Males often mate with more than one female (polygyny), but promiscuity is common as well. Monogamy may be observed among the more social species (e.g., *Pteronura brasiliensis*), but extra-pair copulations may occur as a result of bachelor males expanding the range of their movements during breeding season (e.g., *Meles meles*) (Dugdale et al. 2007; Sandell 1989).

During breeding periods, males usually navigate to females, while females maintain their territories. Initially, navigation is guided by a combination of the male's previous knowledge of the locations of females within their home range and by scent-marks deposited by females in estrus. Latrines can be important indicators of location and reproductive status during this period (Stevens and Serfass 2008). For navigation to receptive females to be successful, males must navigate not only through space but through time as well. If mate-searching behavior fails to align with female receptivity, or daily activity patterns fail to align between the sexes, mating may not occur. Seasonal timing of breeding is likely a result of syncing reproduction with either environmental cues such as photoperiod or

temperature, or syncing with resource availability (Ben-David 1997). When a reproductive male and a receptive female come into close proximity, the female may indicate her location and status through a variety of auditory and visual signals. Males are guided by these signals to approach the female and attempt to mate. In more social species or populations, males and females occupy the same dens and share the same territory. In these cases, navigating to a mate is simpler, though extra-group males may navigate into unfamiliar territories to mate with a receptive female.

## Dispersal

The dispersal of juveniles from their natal home range consists of three processes: emigration from the natal home range, movement between habitat patches, and establishment or immigration to the new home range. Timing of dispersal is inexorably linked to reproduction. After young are weaned they spend time with the mother learning skills such as locomotion, foraging, and how to minimize risk of predation. Eventually they leave their natal grounds in search of a new home range. Considerable variation exists in the timing and distance of dispersal events within a species, and this variation may be explained by factors such as population density and resource availability (Powell 1994). For example, high population densities and low resource availability may result in increased dispersal rates and distances. After leaving their natal grounds, juveniles enter a search phase during which they travel from patch to patch in search of suitable, unoccupied habitat. This search may take the form of exploratory forays or an individual may leave its natal grounds permanently. Mustelids are capable of dispersing great distances relative to their size. For both terrestrial and aquatic species, navigation may be accomplished by following linear features such as fencerows or riparian corridors (Sheffield and King 1994). While searching, perceptual range, or the distance at which suitable habitat may be detected, plays an important role (Lima and Zollner 1996). The ability to detect scent-marks of conspecifics and suitable habitat at greater

distances increases navigational efficiency and may reduce time to home range establishment and risk of predation during dispersal. For home range establishment, search criteria for males may differ from those of females, given their respective needs for defendable territory or habitat suitable for raising young. Ultimately, the location and size of the selected home range is dependent on the availability of resources that contribute to increased fitness for the disperser (Powell 2005).

Causes for dispersal behavior are many, but they can be summarized as either evolutionary or ecological in nature (Bowler and Benton 2005). Mustelid dispersal is usually sex-biased, in which males travel further from their natal grounds than females. This behavior is driven by an evolutionary need to maintain gene flow, reduce inbreeding, and regulate population dynamics throughout species ranges (Bowler and Benton 2005). Ecological drivers of dispersal behavior contribute to the regulation of more proximate factors such as population density, food availability, and resource distribution. Once the decision to disperse is made, navigation plays a central role in how individuals select a home range as well as the timing of the dispersal event.

## Risk Minimization

Navigation is required to facilitate the avoidance of circumstances that are perceived as risky to the individual. Important risk factors for mustelids include predation, interference competition, and anthropogenic disturbance. All species are at risk of predation for at least a portion of their life cycle, but predation tends to be more important for the population dynamics of smaller species (e.g., *Mustela*, *Martes*, *Vormela* spp.) than larger species (e.g., *Gulo gulo*, *Lutra* spp.). Predators include raptors and larger carnivorans. When the predator is a competitor that kills to reduce the sharing of resources rather than to consume prey, this is known as interference competition. This type of competition occurs particularly when the species ranges of several members of the family – and sometimes of a single genus – overlap. In such cases, the subordinate species may navigate

away from the dominant species in both time and space. For example, fishers (*Pekania pennanti*) occasionally kill American martens (*Martes americana*), and martens may respond to fisher presence by adjusting their periods of activity to avoid direct encounters (McCann et al. 2017). Regardless of whether the purpose of the predation event is consumption or competition, vigilance and escape behaviors from the prey species are similar. For example, while traveling some species frequently pause to use audition and olfaction to survey for predators. Upon detection of a perceived risk, the individual may remain in a state of heightened vigilance or may immediately navigate away from the source of the risk and toward a refuge such as a forest canopy, a body of water, or an underground burrow.

Anthropogenic sources of disturbance are often perceived as risky and responses to such disturbance can be similar to responses to predators (Clinchy et al. 2016; Frid and Dill 2002). Regardless of whether the stimulus is benign or harmful, mustelids tend to respond negatively to such disturbances (Cervinka et al. 2015). They rarely occur in urban or human-dominated landscapes (though exceptions do occur e.g., *Martes foina*), and species commonly shift behaviors and/or alter their patterns of space use in response to the alteration or degradation of their habitat (Pereira de Oliveira et al. 2014; Stewart et al. 2016). Avoidance behaviors and mortality events resulting from human disturbance likely contribute to the decline of species ranges and population sizes throughout the family (Ceia-Hasse et al. 2017). Ultimately, navigation in response to risky stimuli plays a critical role in driving the individual-, population-, and species-level responses to changing landscapes.

## Conclusion

Navigation is a critical aspect of the success of many mustelids much as it is for many other vertebrate and invertebrate species. The noteworthy diversity found across the members of Mustelidae is reflected in their approaches to navigation. However, common themes such as a

typical emphasis upon olfaction and the importance of latrines as features used in navigation are apparent. In summary, whether it is used in territory maintenance, foraging, mate-finding, or other capacities navigation is an important consideration in the life history of all members of the family.

## Synonyms

Alterations; Change; Modification

## Introduction

Errors may occur in every process of molecular biology, although at a low rate. A mutation is an error in genetic material. Generally, mutations do not affect the survival of an organism, but there are lethal and beneficial mutations. The accumulation of beneficial mutations leads to the evolution of a species with different environmental conditions.

Mutations may be variations in DNA/RNA sequences or alterations in the coding sequence of a gene. Subsequently, the replication of DNA carries forward the mutation to the next generation in unicellular organisms. In multicellular organisms, only germ cell mutations are passed to the next generation. A mutation in somatic cells transfers to the next descendants of those cells; it is also responsible for the advent of cancer. Because DNA passes a message to RNA and RNA passes it proteins, an alteration in DNA leads to the synthesis of a defective protein.

## Types of Mutations

Alterations of DNA molecules occur in many different ways. The major types of mutations include the following:

**Insertion:** the addition of one or more bases into a DNA sequence

**Deletion:** the removal of one or more bases from a DNA sequence

**Base substitution:** replacement with another base in DNA sequence

**Translocation:** a segment of DNA transferred from one location to another location, on the same or different DNA molecules

**Duplication:** a copy of a segment of DNA is pasted into another location, with the original copy remaining at its original position

However, mutations also occur in gene codes for tRNA, rRNA, and other non-translated RNA molecules. Mutations in these genes have more drastic effects in RNA processing. Furthermore, mutations can also occur in the regulatory regions of a gene. Mutations in these regions can upregulate or downregulate the expression of a protein and lead to distinguished phenotypes.

### Insertion

A gene can be inactivated by the addition/insertion of a foreign base/segment of DNA, which leads to disruption of the reading frame. This inactivation of a gene also depends on the insertion location. If the insertion occurs in the extreme ends of the gene, then a functional protein can still be made; however, an insertion in the middle will be non-functional. An insertion mutation is divided into two parts: one through the mobile genetic element (natural condition) and the second through chemical mutation or an error by DNA polymerase (Frost et al. 2005).

In natural conditions, the insertion is of a mobile genetic element (transposons or retrotransposons) or viral genome. A transposable element has multiple transcriptional termination sites. Therefore, RNA polymerase cannot pass through it without termination of the transcript, which is known as a **polarity effect** (Baba et al. 2006). Occasionally, insertion also activates genes. If the insertion is a repression region of the transcript, binding of the repressor is prevented and the gene is activated. However, some transposon elements have promoters at their extreme ends (facing outward). Therefore, the

insertion is in the upstream of a gene and the genes are activated. An example of a “cryptic gene” is found in *Escherichia coli*, which is inactive in the wild-type and active in the mutant.

### Deletion

The removal of one or more bases from a sequence is known as a deletion mutation. The lethality of this mutation depends on how many bases are deleted. A point deletion has a more drastic effect because it disrupts the reading frame. It is indicated by the symbol  $\Delta$  or DE; for example,  $\Delta(\text{LigA-LigB})$  indicates deletion of a region from LigA to LigB. Obviously, there is no gene, no mRNA, and no protein. If this gene is essential for survival, then the deletion will be lethal. A deletion is not site-specific; that is, the deletion may occur in a regulatory region or a non-essential region between or within the gene (introns).

### Base Substitution

The replacement of one base with another base is a substitution mutation. There are two types of substitutions: **transitions** and **transversions** (Topal and Fresco 1976). In a transition mutation, purine is replaced by purine and pyrimidine is replaced by pyrimidine (i.e., T replaced by C or vice versa). In the case of a transversion mutation, purine is replaced by pyrimidine or vice versa.

When DNA polymerase replicates, this mutated site (mismatched site) is incorporated, such that there is one wild-type daughter and one mutated daughter.

### Duplications, Inversions, and Translocations

A duplication is a simple copy-and-paste of a sequence from one location to another location; the original copy and location are unchanged. A eukaryotic gene is full of tandem repeats, which are generated by either slippage of DNA polymerase or transposon elements (Viguera et al. 2001). During replication of a repetitive sequence, DNA polymerase may skip or revert back and replicate the same sequence again. In the case of a transposon element (retrotransposon), enzymes are required for integration; hence, it integrates into the genome. Our genome is full of retrotransposons (Fig. 1)

**Mutations, Fig. 1 Effect of an insertion mutation.** Immature termination of an operon in a bacterium after the insertion of a transposon element inside gene 2. Only

gene 1 transcribed completely. Gene 2 immaturely transcribed, and gene 3 did not transcribe

As the name suggests, an inversion is the inversion of a segment of DNA. The inversion of a gene discontinues it from a regulatory region (promoter) and has highly detrimental effects. If an inversion fragments all the regulatory and open reading frames, then it has an only mild effect. Sometimes, a chromosome rotates  $180^\circ$  after a double-strand break; when it rejoins, the segment becomes inverted.

A translocation is a change in location of a gene or DNA segment from its original position to another position. Translocation can be intrachromosomal or interchromosomal. If a complete gene is moved from one place to another, it would not cause any issue. However, if a gene is inserted between another gene, then it causes insertional inactivation of that gene and results in double chaotic.

### Missense Versus Nonsense Mutations

In a substitution mutation, a gene coding region leads to a change in codons followed by a change in the amino acid sequence; that is, one amino acid is replaced by another amino acid at the protein level. The severity of a mutation depends upon the replaced amino acid. If the replaced amino acid is similar to the previous one, then it has a very low or non-significant effect; however, if the changed amino acid is different in nature, then it has a drastic effect. Severity also depends on the position of the mutation. A mutation in the active site of the enzyme is more severe in a one-letter code

abbreviation mutation; for example, G153R or Gly153Arg indicates that glycine in the 153rd position was replaced by arginine.

The chemical properties of the replaced amino acid play a significant role in a missense mutation. Suppose the codon GUG, which codes for valine amino acid, changed into GCG, which codes for alanine. If both amino acids are hydrophobic in nature (i.e., have similar chemical properties), then the conversion of GUG into GCG has a minor effect. The replacement of one amino acid with a different amino acid having similar physical and chemical properties is known as a **conservative substitution**, whereas replacement with an amino acid having different physical and chemical properties is known as **radical replacement**.

In a type of substitutive mutation known as a **temperature-sensitive (ts) mutation**, a protein is folded properly at a low temperature (permissive temperature) and unfolded at a higher temperature (restrictive temperature) (Game and Mortimer 1974). This type of mutation is very essential to study the functional properties of essential proteins. If the knockout of that gene is generated, then the organism does not survive. Therefore, in this case, a ts mutation is generated and the organism survives at permissive but not restrictive temperatures.

There are three codons (UAA, UAG, and UGA) that do not code for any amino acid; they are known as **stop codons**. When a substantive mutation converts a codon into any of these stop

codons, it is called a **nonsense mutation**. For example, if the codon UAC code for tryptophan undergoes a substitution mutation and is converted into UAG, this is a stop codon (Liaw et al. 1997). Therefore, when ribosome reads this transcript during translation, it terminates at the tryptophan site that was converted into a stop codon. Thus, this type of mutation is also known as a **chain termination mutation**. Such a truncated protein is detected and degraded by a proteasome complex. If a nonsense mutation is an essential gene, then it has a lethal effect.

### Silent Mutation

When there is a change in the DNA sequence but no change in the protein sequence, this is called a **silent mutation**. Suppose UUU codes for phenylalanine and U is converted into C; therefore, it becomes UUC, which also codes for phenylalanine. When one amino acid is coded by multiple codons, it is called **degeneracy** of the genetic code, which plays a major role in silent mutations. Very often, changes in the third position of a codon have no change in an amino acid sequence; this is called **third-base redundancy**. In addition, a substitution mutation at the third position of a codon may be silent. Third-base redundancy causes no changes in protein sequence but affect the translational level due to a shortage of charged non-preferred tRNA in the tRNA pool. For example, suppose there are six codon codes for leucine, but only one or two codons are preferred in our genome/genes; due to this preference, the concentration of charged tRNA inside a cell is present at different levels. Therefore, if a high-frequency codon is converted into a low-frequency codon for the same amino acid, it may slow down due to a shortage of charged tRNA translation (although sometimes it may speed up).

A mutation in an intervening region of a gene that causes no change in the protein sequence is also a type of silent mutation. If a mutation is at the splicing site of an intron and results in a failure of splicing of intron, it has drastic effects and initiates an evolutionary phenomenon known as **alternate splicing**, which results in a slightly abnormal splice product (Modrek and Lee 2002).

### Mutagens

Agents that cause mutations in DNA are known as **mutagens**. There are three types of mutagens: chemicals, radiation (ionizing), and heat. Chemicals and radiation cause direct and indirect effects that change/modify DNA bases, which further lead to mutations. In an indirect effect, the mutagen directly reacts with nucleotide bases; the product of a mutagen reacts with DNA (like free radicals) (Liaw et al. 1997). A mutation may be **induced** or **spontaneous**. Sometimes, mutation may occur even when there are no mutagens, which is called spontaneous mutation. The enzymes involved in replication and repair may make mistakes.

### Induced Mutations

The most common mutagens are chemical mutagens. They react with a nitrogen base and modify it. DNA polymerase may misidentify these modified bases and add a wrong base in the newly replicated strand. Some examples of chemical and radiation mutagens include the following.

#### Chemical:

Hydroxylamine

Base analog (e.g., bromodeoxyuridine)

Alkylating agents (e.g., N-ethyl-N-nitrosourea (ENU))

DNA adducts (e.g., ochratoxin A)

DNA intercalating agents

DNA crosslinkers

Oxidative damage

Nitrous acid (converts A to C)

#### Radiation:

Non-ionizing radiation (ultraviolet light), which causes the dimerization of two constitutive pyrimidine bases and forms a pyrimidine dimer.

Ionizing radiation. Exposure to any ionizing radiation causes strand breakage and lysis of water molecules, which release free radicals that react with DNA. Alpha has a maximum **linear energy transfer**, so it produces more double-strand breaks; due to the short range, it is less effective. Although gamma has a lower linear energy transfer than alpha and beta, it has

maximum penetration and range, thus making it more harmful.

### Spontaneous Mutations

Spontaneous mutations are very rare but very helpful for evolution. The following changes may occur:

- Depurination: The loss of purine (only nitrogen base) and formation of an apurinic site, which is repaired by base excision.
- Deamination: Hydrolysis of a normal amino group into a keto group in a nitrogen base, such as adenine to hypoxanthine.
- Slipped-strand mispairing: Denaturation and then renaturation of the newly synthesized strand in a different region, causing insertion or deletion.
- Replication slippage: During replication of a repetitive sequence, the DNA polymerase slips backward or forward and changes the number of repeats.
- Tautomerization: Repositioning of a hydrogen atom that changes the hydrogen bonding pattern.

than average, and the type of mutation is also the same; these sites are called **hotspots** (Brash and Haseltine 1982). Most hot spots sites are methylcytosine in genes. After replication, methylation of a newly synthesized strand occurs by methyltransferases; for example, cytosine is converted into methyl-cytosine and pairs with guanine. After deamination, methyl-cytosine is converted into thymine, which pairs with adenine, not guanine. Therefore, when DNA polymerase replicates, it adds adenine instead of guanine and causes a transversion mutation (Fig. 2).

### Detection

The mutagenic effects of a mutagen are checked by the rate of conversion of mutant to wild-type. The **Ames test** uses well-characterized mutants (in the histidine gene) of *Salmonella typhimurium* and the rate of revertant screened on a negative histidine background (Ames 1975). All cosmetics, hair dyes, drugs, food colorings, and preservative are screened by government agencies using this technique.

### Hotspots

A gene may mutate a thousand times, but all the mutations are not on different sites. There are certain sites where the rate of mutation is higher

### Conclusions

Mutations have both advantages and disadvantages in evolution. Without mutations, the evolution of species is not possible. A single mutation

**Mutations,**  
**Fig. 2 Mutation**  
**distribution in a gene.** The frequency of mutations versus the positions of nucleotide bases in a gene. Locations around 12 and 23 base pairs receive more mutational events than other regions

leads to the extension of a species or the emergence of a new species. The rate of mutations (known as the **molecular clock**) varies from organism to organism. The rate of mutations in viruses is high, whereas it is very low (and very difficult to even determine) in humans (Ames 1975). Mutations occur not only at the gene level but also at the chromosome level, affecting the structure, function, and inheritance of the whole DNA.

## Definition

Mutualism is a positive reciprocal relationship between two individuals where both may live together in close physical association.

## Introduction

Every other organism on the planet is an intricate part of the ecosystem and has to interact with various other organisms in the environment for

their requisite survival. This biological interaction not just encourages the survival of species but ensures the smooth functioning of the ecosystem as a whole. Margulis (1971) described the basis of all eukaryotic life, i.e., endosymbiotic mutualism between independent microbes and their cells. Mutualism is one of the three fundamental ways of interaction between two different species of organisms, the two other being commensalism and parasitism. The term “mutualism” was introduced by Pierre-Joseph van Beneden in 1876. This relationship can be within the species, between living things from two different species, between individuals in a society, and between two societies. Each participant in the mutualistic relationship is called a symbiont. Mutualism is a type of symbiosis. Symbiosis is a broad category, defined to include relationships that are mutualistic, parasitic, or commensal. Mutualism involves either the exchange of resources, such as nutrients, food, and shelter or may involve the exchange of services, such as protection or transportation.

### Role of Mutualism

Mutualism is a type of symbiotic relationship where, in brief, it can be defined as a  $+/+$  interaction whereas commensalism and predation are, respectively,  $+/0$  and  $+/-$ . However, not all symbiotic relationships are mutualistic (Boucher et al. 1984). Mutualism occurs in both terrestrial and aquatic ecosystems; as ecologists now believe that each and every species on earth is directly or indirectly involved in one or more of these interactions. Most modern terrestrial ecosystems are critically dependant on mutualism: 90% of land plants exhibit a symbiotic relationship with mycorrhizal fungi, and significantly, all mammalian and insect herbivores inhabit cellulose-digesting symbionts (Smith 1991). The influence of mutualism dates back to the levels of biological organization from cells to populations, communities, and ecosystems. The significance of mutualistic symbioses is linked to many key events in the history of life on earth, including the origin of the eukaryotic cell, invasion of the land, and radiation

of the angiosperms. Mutualism has surely played a crucial role in the ecology and evolution of various life forms on earth.

### Benefits of Mutualism

Mutualisms have long been acknowledged as exchange of benefits among which comprises: (1) nutritional, involving breakdown of compounds by digestion for the partner or supply of nutrients and growth factors by synthesis; (2) providing energy, generally from photosynthesis; (3) protection, either from enemies or from environment; and (4) transport, either from an unsuitable to a more suitable environment or by dispersal of propagules or gametes (Boucher et al. 1984). Symbiotic mutualists usually exchange the first two services, seldom third, and rarely the fourth. Nonsymbiotic usually exchange all four.

### Direct and Indirect Mutualism

Mutualism can be categorized into direct and indirect mutualism. The former involves direct physical association between the two species, and then indirect mutualism, in which each species benefit from the other's presence but there is no direct contact. Direct mutualism is divided into symbiotic and nonsymbiotic, using physiological incorporation as basic criterion. Within mutualism, there are three types: (i) trophic mutualism, (ii) dispersive mutualism, and (iii) defensive mutualism. Each of these three with examples is discussed below.

#### Direct Mutualism

**Symbiotic Mutualism** In case of mutualistic symbioses, the two species lives in close proximity to each other for part or all of their lives. They tend to be coevolved and obligate and thereby cannot lead an independent life. This is the case with the fungus-algae symbiosis called lichens. A lichen is a mat of fungal hyphae inside which dwells a thin layer of cells of photosynthetic algae or cyanobacteria. The algae gains protection from drought and solar radiation from fungus, while the latter receives products of photosynthesis from the algae. Thus lichens can withstand extreme environmental conditions in which neither algae nor

fungus could (Mackenzie et al. 2002). Intestinal flagellated protozoans and termites display obligative mutualism, in which the protozoans digest the food ingested by the termites, where neither can survive without the other under natural conditions. Another example comes from mycorrhizae, the symbiotic association of fungal hyphae with the roots of many species of higher plants, particularly significant in poor soil types. The fungi help plants in the uptake of nutrients (essentially phosphate) while receiving nutrients from the plants.

Gut microbiota in mutualism with many vertebrates (Backhed et al. 2005), termites, and other arthropods are involved in degradation of cellulose and related substances and toxic secondary plant compounds. In numerous associations, they are involved in the synthesis of all of the B-complex vitamins, vitamin K, and sulfur containing amino acids. However, some non symbiotic mutualisms are also obligate, such as those formed by fungus-farming ants, in which neither can survive without the other, and another one being cleaner fish and the “customer” fish from which they remove dead skin and parasites. Endozoic algae harboring in coral zooxanthellae supply ammonia from seawater and bacterial symbionts in green hydra increase uptake of phosphate from the medium. In return, these organisms take up waste products from their hosts and use them for their own growth.

**Nonsymbiotic Mutualism** These are facultative and not coevolved. Both the partners may coexist without a dependence on each other and exhibit opportunistic mutualism. However, exceptions arise in case of anemone-dwelling fishes, which show some physiological habituation to the mutualist. They may be diffuse, involving varying number of species, example being pollinators and their plants. Honey bees visit many different species of flowering plants during the course of the season and many of these plants will be visited by a number of insect pollinators. Similarly, interaction between nitrogen fixing bacteria and plants, such as between legumes and *Rhizobium*, is facultative. Leguminous plants benefit immensely from the nitrogen-fixing activities of the bacteria,

which form nodules in plant roots in nitrogen-poor soils (Mackenzie et al. 2002). However, when soil nitrogen levels are optimum, the plants thrive in their absence.

#### Indirect Mutualism

Theories on indirect mutualism have established that species that never come into close physical contact with each other may however positively affect each other's physical fitness (Connor 1995).

#### Types of Mutualism

##### Trophic Mutualism: Resource-Resource Benefit

Mutualism where both species acquire benefit in the form of resources. Substantial evidence comes from the relationship between the coral polyps and zooxanthellae – a single celled alga which lives within the coral polyps. In this case, coral polyps depend on the photosynthesis process carried out by zooxanthellae, while the latter depend on nitrogen, which the coral polyps derive from hunting at night.

##### Dispersive Mutualism: Resource-Service Benefit

Mutualism in which one partner is dedicated in harvesting a food resource traded for a service. An explicit example is pollination, in which nectar or pollen are traded for dispersal or ant protection of aphids, where the latter trade sugar-rich honeydew in exchange for defense against insect predators such as ladybugs (Bailey 2018).

##### Defensive Mutualism: Service-Service Benefit

Mutualism in which one partner protects the other against predators or parasites and the other returns favor by providing food and shelter. The best example is mutualism between anemone fish (family Pomacentridae) and sea anemones: The anemones provide fish with protection from predators and the fish in return defend against butterflyfish (family Chaetodontidae). Acacia ants (*Pseudomyrmex ferruginea*) reside in bull-horn acacia (*Vachellia cornigera*), wherein the ants obtain food and shelter inside the plant's thorns and acacia depends on the ants for protection from browsing animals.

## The Evolution of Mutualism: Considering the Alternatives

Since past few years, ecologists have acknowledged the connection between global change and ecological species interaction (Kiers et al. 2011), notably plant-pollinator interactions. While mutualistic interdependence has paved way for many evolutionary opportunities, it also becomes a necessary evil: because mutualisms aggregate multiple species to a common fate, the significant breakdown of these interactions will amplify the effects of global environmental degradation and other causes of species extinction. For example, the intensely debated topic “Adaptive Bleaching Hypothesis” which signifies coral bleaching (i.e., exclusion of zooxanthellae partners from their coral reef hosts) (Jones et al. 2008). However, exclusion of the mutualistic zooxanthellae and increased susceptibility to fast growing symbionts reflects flexibility in mutualism management. Sometimes mutualism leads into unbalanced exploitation of one symbiont to the benefit of the other-parasitism. For example, many orchids tender no reward for their pollinator and instead use them to perch on the flower to mimic female insects by using scent and color patterning. Mutualisms are dynamic and scientists wonder the indefinite persistence and stability of many mutualisms. However, many have been formed and dissolved over evolutionary time scales undergoing changes in the important trajectories of mutualism: (1) shifts from mutualism to antagonism, (2) evolutionary changes of novel partners, and (3) mutualism desertion (i.e., extinction of the interaction, but not necessarily partners).

## Myelination

Mallahalli S. Manu  
Department of Biochemistry, Davangere  
University, Davangere, Karnataka, India

A thick insulating structure derived by the glial cells around the axons of neuron cells in the nervous system is called myelin. The overall event of myelin formation is called myelination.

Myelin was first described by Rudolf Virchow in 1864. It is made up of 70% of lipid (neutral

lipids, phosphoglycerides, sphingolipids) and 30% of proteins (majorly glycoproteins). Myelin sheath is derived from the plasma membrane of the glial cells. In the central nervous system (CNS), it is formed by oligodendrocytes, while in the peripheral nervous system (PNS), it is formed by Schwann cells. It is not that all the axons of vertebrate is myelinated, even the non-myelinated axons have their role in nervous system. The fundamental role of myelin sheath is to fast conduction of action potential along the neurons which it insulates (Fields 2014). There will be a periodic gap in the myelin sheath between adjacent myelin segments – node of Ranvier. These gaps or nodes are rich in sodium and chloride ion channels. Action potential is triggered at these nodes and passively move to the next node where the next action potential is generated; this jumping of action potential from node to node results in rapid conduction of nerve impulses (Kettenmann and Verkhratsky 2011).

### Early Events in Myelination

Myelination is a complex molecular process that requires precious coordination between several cellular signaling molecules and cascades. Glia-axon interactions are potentially vital throughout the event of myelination. Signaling molecules like neuregulins, neurotrophic factors, transcription factors, and survival factors are required in myelinating of axons (Feltri et al. 2016).

Early events in myelination involve different morphological stages, where every stage is highly controlled and well executed by the specific signaling molecules both in the central and peripheral nervous system (Fig. 1).

### Myelination in CNS

In the CNS, myelination process is carried by the oligodendrocytes and their precursor, where single oligodendrocyte can myelinate multiple axons; therefore, it is called as multipolar glia. Myelin sheath is formed by the plasma membrane of oligodendrocytes that spirally wrap around the axon that have a diameter of more than 0.2  $\mu\text{m}$ , to form thick insulating structure of around 40 segments (Simons and Trajkovic 2006). Oligodendrocytes are developed from oligodendrocyte progenitor cells (OPCs) that divide and migrate to the appropriate destination from their germinal region, and then initiation of myelin component's synthesis will take place. Later myelin wrapping will be initiated, followed by compaction of myelin structure by mature oligodendrocytes. Many extrinsic and intrinsic signals control the oligodendrocyte differentiation and myelination (Emery 2010). Signaling molecules like neuregulins-1 (NRG1), laminin, PDGF, IGF, NT, and Notch-1 (Barres and Raff 1999) are expressed during the myelination in the CNS. Recent studies on the role of oligodendrocytes have proven that initiation and continued myelination can be done

**Myelination, Fig. 1** Early events of myelination in the CNS and PNS. (a) Bundles of axons are closely associated with glial cells. (b) Glial cells surround the single axon. But the mesaxon is not yet completely fused but portion of

axon is engulfed. (c, d) The mesaxon is fused in the initial stage; later the glial cells begin to rotate around the axon to form few layer of myelin. (e) Myelin completely wraps around the axon to form tightly packed myelin sheath

by oligodendrocytes in the absence of neurons. This proves the major function of oligodendrocytes in myelinating the axons of CNS.

## Myelination in PNS

Schwann cells are the glial cells of the PNS; their plasma membrane differentiation forms the myelin sheath around the axons of peripheral neurons. In PNS, a single Schwann cell will myelinate a single axon. Neuronal crest cells are the stem cells which generate the Schwann cell precursors that migrate along the axons extending to their target. In the next step, this Schwann cell precursor gives rise to immature Schwann cell which performs the radical sorting of axons. This allows the axons to build one-to-one relationship stable contact between the axons and Schwann cells. Later Schwann cells which are in promyelinating stage will form the tight wrapping of myelin around the axon to form myelinated Schwann cell. The signaling molecules like nucleic acid-binding (NAB) protein, Sox-10, Krox-20, Oct-6, Brn1, and Brn2 are involved in the myelination of peripheral neurons (Jessen and Mirsky 2005).

## Conclusion

Myelination is a step-by-step event that is highly coordinated by several intrinsic and extrinsic factors. Many neuropathic diseases exhibit the

demyelinated morphological characteristic that fails in normal conduction of nerve impulse. Thus myelin development and their maintenance are considered very crucial in healthy individuals. Still the cellular and molecular mechanisms involved in myelination and their maintenance are likely to be key area for further research.

## Main Text

Bodies donned in black pelts and beaded necklaces swarm in a hostile crowd. Shrill invectives

are hurled across a dirt courtyard encircled by thatched longhouses. The tension between groupings around this courtyard heightens, weapons are brandished, and violence ensues, one man striking another on the head with the blunt side of an ax. This is the opening scene of “The Ax Fight,” one of the best-known works of anthropologist Napoleon Chagnon, then a graduate student at the University of Michigan. By initially providing no interpretation, Chagnon intended to create for the viewer the experience of observational naïveté upon watching the behaviors of an unfamiliar group of people, much as a naturalist might watch a pride of lions. This unfamiliar group was the Yanomami, an Amazonian indigenous group living on the border of Venezuela and Brazil. Chagnon researched the Yanomami from the mid-1960s to the late 1990s and was both applauded for his in-depth study of the cultural group and groundbreaking analyses of its members and denigrated for his resultant conclusions about “human nature.” Utilizing observational strategies from ethology and applying Darwinian theory to human behavior, Napoleon Chagnon has concluded that “nature, red in tooth and claw” holds for humans as well as the other organisms on Earth, that competition is the primary directive of human action and, therefore, violence is fundamental to social groups.

In the film, Chagnon, a student of Leslie White who reintroduced theories of cultural evolution to anthropology in the mid-1900s, displays kinship diagrams after the unedited footage of the

Yanomami conflict plays and then replays the footage in slow motion, describing the familial relationships between the main actors. He demonstrates, drawing on kin selection theory from animal behavior studies, that this fight is structured by kinship; combatants choose sides based on genetic relatedness. This is not merely a chaotic brawl. Kin selection theory posits that an individual's behavior will support other closely related individuals, as those actions will ensure the reproduction of the individual's genetic material in the next generation. In "The Ax Fight," Chagnon reveals to his viewers that the fight results from long-standing hostility between a group of closely related individuals in the village and another visiting group of related individuals. In a published 2013 interview with Napoleon Chagnon, he stated, "I began using commonly known ways to 'measure' relatedness between organisms – Sewall Wright's coefficient of inbreeding and its extended concept, the coefficient of relatedness. This was very unusual in cultural anthropology" (Iannone 2013, p. 260).

Not only was Chagnon's work unusual in cultural anthropology at the time, it was extremely controversial. Two of his major works – an early 1968 monograph, *The Yanomamö: The Fierce People*, and a 2013 retrospective, *Noble Savages: My Life among Two Dangerous Tribes – the Yanomamö and the Anthropologists* – sent shock waves through the discipline. Chagnon was denounced as a biological determinist and dismissed by many. However, in 1975, biologist Edward O. Wilson published *Sociobiology: The New Synthesis*, which explained the evolutionary basis behind such social behaviors as altruism and aggression. Wilson's formidable text argued that there really is no distinction between social and biological aspects of human life. Due to the rise in popularity of sociobiology following Wilson's publication, Chagnon's work garnered more respect in scholarly circles. In the 2013 interview, he said, "Wilson's Sociobiology brought to anthropology – and other social sciences – a new and fresh way of looking at human behavior and attempted to make it more comprehensible in the context of primate evolutionary tendencies" (Iannone 2013, p. 262).

Critics of Chagnon's research methods and analyses include anthropologists, natural scientists, and journalists. A relatively small faction of anthropologists have gone on to use evolutionary theory to explain human behavior in recent decades, leading to influential theories like optimal foraging theory and costly signaling theory, but many cultural anthropologists disagree with pushing culture and social learning to the background, except where these processes are individually adaptive. Furthermore, many critics are uncomfortable with the axioms about human nature that result from sociobiological explanations of human behavior – humans are inherently selfish, human behavior is driven by self-interest and profit maximization, competition and violence are innately human. Anthropologist Brian Ferguson (1995) refutes Chagnon's assertion that humans are inherently or "naturally" violent, arguing that Yanomami warfare is a more recent cultural artifact of the violence of European colonialism. Others question the veracity of Chagnon's data, critiquing his statistical methods (Albert 1990) and the effect of his presence on the behavior of the people he observed, particularly because he and his film crew distributed highly-prized and sought-after goods like machetes and other steel wares to individual Yanomami. Anthropologist Marshall Sahlins (2000) went so far as to say that Chagnon's trade of goods for genealogical information amounted to "participant-instigation."

Despite these controversies, Chagnon continues to be an active scholar, contributing to social ethology and cultural anthropology. He retired from the University of California, Santa Barbara in 1999 and was elected to the National Academy of Sciences in 2012. He then joined the faculty of the University of Missouri's Anthropology Department as a "Distinguished Research Professor and Chancellor's Chair for Excellence in Anthropology" and became an adjunct research professor at the University of Michigan's Institute of Social Research. His work with the Institute involves digitizing and archiving his papers in a permanent data repository and translating decades of Yanomami audio recordings into English. Further, in a 2014 publication alongside colleagues at

the University of Missouri, Chagnon compares and contrasts Yanomami patterns of coalitionary violence to that of chimpanzees. In this recent work, the results of the testing “support the strategic alliance model of coalitionary aggression, demonstrate the complexities of human alliance formation, and illuminate key differences in social structure distinguishing humans from other primates” (Macfarlan et al. 2014, p. 16662). While again humans are viewed through a lens typically reserved for the study of animal groups and behaviors, Chagnon and team ultimately conclude that humans are distinct from other primates at least insofar as there are social structural explanations for coalitionary aggression as well as genetic explanations. Just how distinct humans are from the rest of the animal kingdom and the relationship between cultural and genetic drivers of behavior are important questions in the discipline of anthropology, and Napoleon Chagnon has had a long career of pushing the boundaries of investigation.

## Nash Equilibrium

Joseph Taylor

Oxford Brookes University, Oxford, UK

## Synonyms

[Predicting rational behavior](#)

## Definition

In an  $N \in \mathbb{N}$  player normal form game, a Nash equilibrium is a set of strategies for which no player has an incentive to deviate from their current strategy.

## Introduction

Game theory can best be described as the study of interactive decision-making through the use of a variety of mathematical analytic methods (Osborne and Rubinstein 1994a). Game theory lends itself to a number of applications, including life sciences such as conservation, the study of evolutionary biology, and the study of animal cognition and behavior.

A Nash equilibrium, a cornerstone term that appears throughout game theory is used to predict a strategy profile for a given game, or interaction, between  $N \in \mathbb{N}$  decision-makers. In game theory, the term “strategy profile” refers to the strategies used by each player in a given game. Most importantly, at the Nash equilibria, no player has an incentive to deviate from their current strategy.

In order to fully understand the term Nash equilibrium, it is first essential to understand some of the simplest terms associated with game theory.

### Normal Form Games

An  $N$  player normal form game can be defined as a game consisting of:

- A finite set of  $N$  players
- A finite set of strategies available to each player  $i \in N$ ,  $S_i$
- A payoff function for each player  $i$ ,  $u_i: S_1 \times S_2 \times \dots \times S_N \rightarrow \mathbb{R}$ , which maps a strategy profile to a real number corresponding to the utility received

The representation of such normal form games will become more clear in the subsequent section.

### Common Knowledge of Rationality

A key aspect of game theory is the assumption that all players are rational. The following chain of assumptions is known as common knowledge of rationality and is essential in attempting to predict rational behavior (Knight 2017a):

- All players are rational.
- All players are aware that all other players are rational.
- All players are aware that all other players are aware that they are rational.
- And so on.

### Pure Strategies and Mixed Strategies

In a decision-making game, players have the option of adopting a pure strategy whereby the strategy that they choose to use in a given game will be identical for any iteration of that same game. An alternative is for players to adopt a mixed strategy. A mixed strategy is a probabilistic distribution of the player's strategies.

Mathematically, we define a mixed strategy for a player  $i$  as  $\sigma_i \in [0, 1]_{\mathbb{R}}^{|S_i|}$ , where  $\sigma_i$  is a probability distribution over the pure strategies of a player (Knight 2017b). With this definition, it follows that:

$$\sum_{i=1}^{|S_i|} \sigma_i = 1$$

Since probabilities are continuous, there are infinitely many mixed strategies available to all decision-makers.

### Best Responses

A best response in a given game of pure strategies is a strategy that maximizes or minimizes, depending on the game, a player's utility given the opposing player's strategy. Subsequently, a pair of best responses identified in a game of pure strategies is defined as a Nash equilibria.

Mathematically, "in an  $N$  player normal form game, a strategy  $s^*$  for a player  $i$  is a best response to some strategy profile  $s_{-i}$  if and only if

$$u_i(s^*, s_{-i}) \geq u_i(s, s_{-i})$$

for all  $s \in S_i''$  (Knight 2017c, ¶2). Here,  $s_{-i}$  represents an incomplete strategy profile for all other players considered in the game. For example, in an  $N$  player normal form game where  $S_i = \{A, B\}$  represents the strategies available to player  $i$ , a valid strategy profile is  $s = (A, B)$ , for all  $i$ . Therefore,  $s_{-2} = (A)$  denotes the incomplete strategy profile where the first player utilizes the strategy A, and the strategy utilized by player two is undetermined (Knight 2017a).

### Nash Equilibria

According to Knight (2017d, ¶2), "in an  $N$  player normal form game, a Nash equilibrium is a strategy profile  $\tilde{s} = (\tilde{s}_1, \tilde{s}_2, \dots, \tilde{s}_n)$  such that:

$$u_i(\tilde{s}) \geq u_i(\tilde{s}_i, \tilde{s}_{-i})$$

for all  $i$ ." Again, at the Nash equilibria no player can deviate their chosen strategy in such a way that benefits their utility given the actions of the other players (Osborne and Rubinstein 1994b).

### Examples

With the use of the preceding definitions, the Nash equilibria of the following normal form games can be obtained.

### Nash Equilibria in Pure Strategies

Consider the following version of the classic hawk-dove game, first developed by J.M. Smith and G.R. Price (1973), to illustrate how the Nash equilibria is obtained in a game of pure strategies:

There are two birds of prey, who are assumed to have equivalent attributes, and who have both identified a potential food source. The birds of prey have the option of acting like a hawk or a dove. It is assumed that hawks are willing to fight relentlessly over the resource, leading to injury to both themselves and their opponent. In contrast, doves are much more passive and are willing to share a single resource (Table 1).

The arbitrary figures in this example can be interpreted as follows: if both birds are to act like hawks, the birds yield a negative utility through injury inflicted by the other bird. In the case that one bird acts like a dove whilst the other acts like a hawk, the dove retreats and the hawk eats the entirety of the prey. When both birds take on the role of a dove, the resource is shared equally.

Through identifying best responses to each possible strategy, it is possible to predict a rational outcome of this game. If the first bird is to act like a hawk, the best response for the second bird is to act like a dove, since  $0 > -1$ . In the instance that bird 1 acts like a dove, the utility is highest for bird 2 when taking on the role as a hawk, since  $1 > 0.5$ . Since in this case the utilities yielded by each player are independent of which player chooses the action, the best responses are identical for both players. Therefore, this game yields Nash equilibria in pure strategies, those being (Hawk, Dove) and (Dove, Hawk). Hence, in a population of birds of prey who primarily take on a role as a hawk, an individual would yield the highest utility by taking on the role of a dove. In contrast, in a population of birds of prey who primarily take on a role as a dove, an individual would yield the highest utility by taking on the role of a hawk.

### Nash Equilibria in Mixed Strategies

Now, consider the same game with the same payoffs, but where both bird 1 and bird 2 adopt

mixed strategies. In order to obtain best responses against mixed strategies, it is required to first obtain the player's expected utilities. In order to do so, the utility function is relied upon. Knight (2017b) defines the utility function for a two-player normal form game as follows:

$$u_i(\sigma_1, \sigma_2) = \sum_{r \in S_1, c \in S_2} \sigma_1(r) \sigma_2(c) u_i(r, c)$$

Assume that the first bird takes on the role of a hawk  $x$  percent of the time and takes on the role of the dove the remaining  $(1 - x)$  percent of the time. This can be defined by  $\sigma_1 = (x, 1 - x)$ . Then it follows that:

$$\begin{aligned} u_2(\sigma_1, \text{Hawk}) &= x(-1) + (1 - x)(1) \\ u_2(\sigma_1, \text{Hawk}) &= 1 - 2x \end{aligned}$$

and that,

$$\begin{aligned} u_2(\sigma_1, \text{Dove}) &= x(0) + (1 - x)(0.5) \\ u_2(\sigma_1, \text{Dove}) &= 0.5 - 0.5x \end{aligned}$$

Using the mixed strategy algorithm, any mixed strategy that exists that makes the other player's decision over which strategy to play indifferent can be identified (Spaniel 2012). Therefore, it follows that the expected payoff for a player will be the same regardless of the strategy adopted by the opposing player. Hence:

$$\begin{aligned} u_2(\sigma_1, \text{Hawk}) &= u_2(\sigma_1, \text{Dove}) \\ 1 - 2x &= 0.5 - 0.5x \\ x &= 1/3 \end{aligned}$$

and therefore,

$$1 - x = 2/3$$

yielding that,

$$\sigma_1 = (1/3, 2/3)$$

This can be illustrated graphically as follows (Fig. 1):

Here,

- If  $x < 1/3$ , then acting like a hawk is a best response for bird 2 since it will yield a higher utility.

**Nash Equilibrium, Table 1** Hawk-dove game, with expected payoffs

| Bird 1 | Bird 2     |              |
|--------|------------|--------------|
|        | Hawk       | Dove         |
| Hawk   | $(-1, -1)$ | $(1, 0)$     |
| Dove   | $(0, 1)$   | $(0.5, 0.5)$ |

**Nash Equilibrium, Fig. 1** Graphical representation of the expected payoffs for bird 2

- If  $x > 1/3$ , then acting like a dove is a best response for bird 2 since it will yield a higher utility.
- If  $x = 1/3$ , then bird 2 is indifferent.

Since the game is symmetric, it is clear that:

$$\sigma_2 = (1/3, 2/3)$$

Therefore, a Nash equilibria has been identified in mixed strategies. That is to say that both birds adopt the role of a hawk one third of the time, and adopt the role of a dove two thirds of the time, denoted  $((1/3, 2/3), (1/3, 2/3))$ . At this point, neither bird has an incentive to deviate from their strategy.

### Nash's Theorem

Nash's theorem states that any game with two or more players and a finite number of strategies available to the players has at least one set of strategies where no player is able to improve their utility by independently changing their strategy (Weisstein 2019). That is, a Nash equilibrium exists for every such game. Therefore, if a pure strategy Nash equilibrium does not exist, one must exist in mixed strategies.

### Conclusion

As highlighted, the concept of Nash equilibrium is incredibly useful in attempting to predict an

outcome for a given interaction between rational decision-makers. For example, in more complex dynamic games than those outlined in this paper, the Nash equilibria can be used to attempt to predict potential evolutionary adaptations whereby organisms who adopt "successful" strategies will out compete those who do not (Gintis 2009). This notion is incredibly powerful and effectively highlights the fact that Nash equilibria, along with numerous other game theoretic tools, can be utilized to provide insight into the cognitive processes in animals which lead to their behaviors, and even an overall insight into how the natural world operates and adapts.

## Nathan Emery

Nathan J. Emery

Queen Mary University of London, London, UK

Nathan Emery is a comparative psychologist with a strong background in neuroscience. He was one of the first UK students to take a Bachelor's degree in Neuroscience, at the University of Central Lancashire, Preston (1990–1993). In 1994, he worked on his PhD with David Perrett on neurons in the superior temporal sulcus of rhesus monkeys tuned to social signals, such as eye gaze direction and intention movements. After completing his PhD in 1997, he moved to the University of California, Davis, working with David Amaral on the role of the amygdala in primate social behavior. Here he met his future wife and collaborator, Nicky Clayton, and his research interests started to change from the brain to cognition and from primates to birds, specifically corvids. In 2000, Emery and Clayton moved to the University of Cambridge; Emery continued his research on the neurobiology of primate social behavior with Barry Keverne at the famous Sub-Department of Animal Behaviour working on the role of the amygdala and prefrontal cortex in marmoset parental and sexual behavior, but he increasingly devoted more of his time to studies of caching behavior in western scrub jays with Clayton. This latter work resulted in a paper published in *Nature*, which may be a first in science. The two authors are married and share the same birthday and the paper was published on their joint birthday! In 2002, Emery was awarded a prestigious University Research Fellowship from the Royal Society. This gave him 8 years of funding and freedom to pursue research to support his now celebrated theory that corvids are “feathered apes” because of their similar cognitive abilities with the great apes.

In 2007, Emery moved to Queen Mary University of London to become Senior Lecturer in Cognitive Biology and assist with the development of a new Bachelor's degree in Psychology, as well as establish a research center in psychology with a strong comparative and evolutionary focus.

During this time, Emery started a new research program on parrot cognition with his student Jayden van Horik, establishing groups of Hahn's macaws and black-headed caiques. He has also worked with the iconic Tower of London ravens. He has served on the editorial boards of *PLoS ONE*, *Communicative & Integrative Biology*, *Frontiers in Comparative Psychology*, *Journal of Comparative Psychology*, *Current Directions in Behavioural Sciences* and *Animal Cognition*. Recently, he wrote and illustrated a popular science book called *Bird Brain: An Exploration of Avian Intelligence* (Emery 2016) which has now been translated into German, Spanish, Korean and Japanese. A long bout of ill health prevented Emery from taking a more significant role in experimental research, but he continues to play an active role in the comparative psychology community, especially with respect to public engagement.

Although he started as a neuroscientist and later switched to comparative cognition, he has always maintained an active interest in the brain, especially in how our understanding of neuroscience can inform our understanding of animal minds and vice versa. There are a number of areas to which he has made important contributions:

### Eye Gaze as a Complex Social Signal

When Emery started his PhD, Perrett had already found that some neurons in the monkey temporal lobe were selectively responsive to the perception of another's gaze direction; some tuned to gaze looking right, others to gaze looking left, and others to gaze directed at the viewer. However, these neurons were strange because monkeys did not seem capable of using eye gaze as a social cue, for example, to locate hidden food. This was important, because studies of the primate brain were being justified ethically for their utility as a model of the human brain. For example, understanding the system involved in computing where another is looking may be used to model social deficits in individuals with autism. Emery therefore attempted to resolve the issue of why monkeys had failed to respond behaviorally to eye

gaze direction cues, when their brains responded automatically to such cues. Through using conspecifics as stimuli, presented as short video clips, as well as recording the subjects' eye movements, he found that monkeys used eye gaze direction to look at objects viewed by another monkey (Emery et al. 1997). He followed this up with a comparative review on gaze processing, breaking it down into subcategories, as well as reviewing the neurobiology of eye gaze. This review has been cited over 1250 times (Emery 2000). Emery continues to work on eye gaze but in birds. He and his PhD student, Auguste von Bayern, found that jackdaws distinguish between different human attentional states when making decisions about when to steal food but only when the human is a stranger, not a caregiver (von Bayern and Emery 2009). Jackdaws can also use eye gaze and pointing cues to locate hidden food from both humans and conspecifics, but only when the cues are deliberately communicative, such as when moving attention from the viewer to the attended object.

### **Role of the Amygdala in Primate Social Behavior**

Studies by Arthur Kling in the 1960s and 1970s had focused the idea that the amygdala plays an important role in primate social behavior. Amygdala-lesioned monkeys acquired devastating social deficits; losing their dominance status and becoming socially isolated. However, such studies were fraught with interpretational problems, as the lesions were crude, damaging more than the amygdala, including fibers of passage, and the surrounding cortex, hippocampus, etc. A more selective procedure was required to destroy only the amygdala, leaving everything else intact. Ibotenic acid, a selective neurotoxin, fulfilled this role, with MRI-guided lesions to make sure that only the amygdala was damaged. Finally, the behavioral analyses performed by Kling (who was a psychiatrist, not an expert in primate behavior) were rather simplistic. David Amaral therefore assembled a team of neurosurgeons, anatomists, and primatologists to determine the detailed

behavioral deficits resulting from precise amygdala lesions. Emery had a detailed knowledge of primate brain anatomy and function, as well as an in-depth knowledge of primate social behavior, and so facilitated communication between the neuroscientists and primatologists on the team. They found that amygdala lesions did not cause the social isolation previously described. Conversely, the amygdalectomized monkeys were more socially attractive, being more approachable, perceived as less threatening, and more likely to elicit affiliative behavior in others (Emery et al. 2001). The lesions appear to have dampened the natural inclination for adult rhesus monkeys to attack strangers. Studies in larger social groups found similar effects, and this research has continued to focus on social development (albeit without Emery).

### **Cache Protection Strategies as Social Cognition**

Although the exceptional long-term memories of caching birds had been a popular target of ethological research, very little was known about another threat to successful cache recovery: cache pilfering. Evidence suggested that corvids were different from other caching animals, as they could observe another bird caching, and remember the location of their caches when they came back to them later without the original cacher present, i.e., they had observational spatial memory. Such a skill meant that caching corvids had to implement strategies to minimize cache theft. Following on from Clayton's seminal studies on episodic-like memory in scrub jays, Emery and Clayton found that scrub jays would cache when observed by another bird but attempt to reduce potential cache theft by coming back alone and moving their original caches to new sites (Emery and Clayton 2001). Most intriguingly, this re-caching was only seen in birds that had previous experience of being thieves themselves. The implications for this are that the caching jays may be capable of projecting the specific past experience of pilfering onto another bird with the potential to steal their caches. This is akin to

simulation theory of mind, where an individual models another's future actions based on their own experience, using this model to make predictions about what they may be thinking, "putting oneself in another's shoes [when they have worn the same shoes themselves]." In a series of follow-up experiments, Emery, Clayton, and PhD student Joanna Dally found that scrub jays utilized a number of different cache protection strategies, such as caching at a distance, caching behind barriers, and caching in darkened areas. They also appeared aware of who was watching and what they had observed, being more selective in their strategies when specific individuals had spied specific caches being hidden or the individual spy had changed (Dally et al. 2006).

### Convergent Evolution of Cognition

A trickle of studies on corvid cognition over the last 30 years, primarily on complex forms of memory, suggested that corvids were vastly more intelligent birds than had previously been appreciated. Corvid brain size, relative to their body size, was found comparable to that of the great apes, with crows having brains relatively the same size as chimpanzees. Emery and Clayton reviewed evidence from studies of tool-using New Caledonian crows, social cognition in western scrub jays, and long-term memory in pinyon jays and Clark's nutcrackers, amongst others, and concluded that the cognitive abilities of members of the corvid and ape families were strikingly similar. They suggested these similarities had arisen independently in the two groups separated by 300 million years, as thousands of close relatives do not demonstrate the same cognitive skills (Emery and Clayton 2004). It is very likely, but not yet known, whether both families had to face similar socio-ecological problems in their recent evolutionary histories, and whether specific selection pressures, such as trying to locate hidden food distributed across wide swaths of time and space, would have driven the evolution of brains and intelligence capable of overcoming such pressures. Studies on corvid cognition, and direct comparisons with great apes, have

blossomed in the years following Emery and Clayton's hypothesis.

### Tasks for Testing Physical Cognition in Non-tool-Using Birds

Emery has been at the forefront of designing cognitive tasks to specifically test physical problem-solving in species that do not use tools. Tool use has been proposed as a specific driver of cognitive evolution, as the ability to use tools is said to require skills in causal reasoning and object manipulation not found in species that do not use tools to procure their food. However, one problem with this assertion was that all tests for physical cognition, such as the classic trap tube task, were designed to only test tool-using animals, i.e., subjects had to insert a tool into an apparatus in order to procure the treat inside. Emery, Clayton, their PhD student Amanda Seed, and Sabine Tebbich designed a new version of the trap tube task which included a pre-inserted tool, so that the subject only had to decide which side to pull (i.e., the side that would lead to the treat being removed from the tube or the other side that would result in the treat falling into a trap). They also included a number of elegant additional designs, such as a nonfunctional trap and a series of controls to remove the use of simple rules as a winning strategy, such as pull from the side furthest from the trap. They found that rooks, a crow that does not use tools in the wild, rapidly learned to pull the inserted stick from the correct side and did so much faster than tool-using chimpanzees. They transferred immediately to novel designs, with one rook passing all controls (Seed et al. 2006). Emery and his student, Chris Bird, then went on to design a number of other physical cognition tasks that could be used to test non-tool-using species for different aspects of their physical cognition, such as the collapsible platform task (Bird and Emery 2009a), *Aesop's Fable* (or water displacement; Bird and Emery 2009b) task, and the peephole task, measuring looking time in birds. These tasks revealed hitherto unknown abilities in rooks. Bird and Emery (2009a) also found that rooks could make

complex tools, such as bending wire into hooks to reach food located in a small bucket at the bottom of a vertical tube (Bird and Emery 2009a). This had only been previously demonstrated in one captive New Caledonian crow, whereas four rooks solved the task on the first trial it was presented, with no natural propensity to make hook (or any) tools.

## Natural Selection

Elena Racevska

Department of Social Sciences, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, UK

Natural selection is a process by which organisms that are better adapted to specific pressures of their environment tend to survive longer and produce more offspring, thus ensuring the preservation and multiplication of those favorable traits through generations, at the expense of the less advantageous ones. It is one of the key mechanisms of evolution, which affects organisms in every aspect, from their physiology and morphology, to behavior and ecology. The term was popularized by Charles Darwin (Darwin 1859).

Natural selection has been incorrectly called “survival of the fittest,” but rather than to the survival, it refers to a *differential reproductive success* of organisms who do and do not carry

beneficial traits that affect how many descendants they will leave.

## The Maturation of the Idea of Natural Selection

The idea of species changing over time long predates Darwin's theory of evolution by natural selection, and it is possible to follow its development back to the ancient Greece. Anaximander suggested that all life forms, including human ancestors, came from water. Empedocles believed that both animals and plants were formed from disconnected parts that would come together in different combinations. Those combinations that were the most adapted survived, while the strange ones became extinct. Plato believed in essentialism and proposed a *theory of Forms*, or *theory of Ideas*, which argued that non-physical forms (ideas) represent the most accurate reality (Ross 1951). Aristotle created *scala naturae* (also known as the *Ladder of Life* or the *great chain of being*), which he used to explain the relationships between all living organisms, placing them on this scale hierarchically, with regard to their structural and functional complexity. He believed that all organisms were designed for a purpose, thus rejecting Empedocles' view of all organisms originating by chance (Charlton 1983).

While Middle Ages philosophy emphasized the role of divine guidance in the creation and development of life, renaissance naturalists maintained that this development was mechanical (Bowler 1989). In the Age of Enlightenment, these ideas were further developed. Carl Linnaeus, a Swedish botanist and taxonomist who came up with the taxonomic system of binomial nomenclature, believed that God created a small number of species, which then interbred and produced hybrids that became new species (Bowler 1989). Comte de Buffon, a French naturalist, rejected Linnaeus' ideas, proposing that species and even individuals within them differed. He defined a species as a group of animals that were able to produce fertile offspring. He was also the first to suggest a possibility of all animals descending from a single breeding pair. James Hutton, Scottish naturalist and the

father of modern geology, advocated uniformitarianism – the assumption that the laws of the universe that operate at present are stable across time and space – for all living organisms, suggesting natural selection as a mechanism that may be affecting them. He believed that species formed varieties, some of which made them better adapted to particular environments, distinguishing between heritable and nonheritable variations. Traits that are passed down from parents to offspring are referred to as *heritable traits*. On the other hand, *non-heritable* or *acquired traits* are obtained through individual's actions (e.g., developing large muscles or higher flexibility through exercise) or are a result of learning (e.g., certain food type preferences or seeking a particular hiding place to avoid a predator).

Erasmus Darwin, an English physician and Charles Darwin's grandfather, suggested that all living organisms, from plants to animals, have a common origin. He believed that a “living filament” is the cause of all organic life. This “great first cause,” as he called it, granted the organisms the power to acquire new parts and improve their inherent activity over generations (Darwin 1794). His most important publication is *Zoonomia* (Part I published in 1794, Part II published in 1796), wherein he explains how species should be spread through the proliferation of the strongest and most active animals in order to improve. This view is today regarded as the *survival of the fittest*.

In 1809, a French biologist Jean-Baptiste Lamarck proposed a theory of the *transmutation of species*. Lamarck believed that living organisms were continuously created by spontaneous generation, and that their increasing complexity was prompted by an innate life force. He did not believe that all organisms shared a common ancestor, but he recognized the adaptedness of species to their environment. However, he presumed that the organisms changed depending on the organs they used or disused, and these changes would be passed down to the next generation, producing adaptations to the environment. This idea that organisms can pass on the acquired characteristics to their offspring is known as *Lamarckism* or *Lamarckian inheritance*, or *soft inheritance*.

In 1813, William Charles Wells read a paper before the Royal Society in which he explained the principle of natural selection in humans. Studying how different breeds of production animals are bred through an artificial, human-orchestrated selection of the best individuals, he realized that an equally efficient, albeit a slower, process is carried out by nature on humans. Wells was interested in the emergence of human races. He proposed that they arose from accidental varieties and those that were best suited to a particular country's climate and diseases became the most prevalent (Wells 1818). Charles Darwin and Alfred Russel Wallace were not aware of Wells' work at the time of publishing *On the Origin of Species*, but Darwin later acknowledged Wells for being the first to recognize the principle of natural selection. He, however, also recognized the limits of Wells' conclusions, as he only noted the natural selection in humans, and only in respect to race.

Edward Blyth, an English zoologist, also discussed artificial selection of production animals, as well as recognized the within-species variation in nature, but he did not see it as a potential for formation of new species, but rather as a way to preserve the one that already exists (Blyth 1835). He believed that natural selection operates on within-species variations by removing those that were less suited for the species' natural habitat than the "original" form, which was without modifications. He also did not believe in a shared ancestry of species.

In 1844, Robert Chambers, a Scottish publisher and author, anonymously published *Vestiges of the Natural History of Creation*. Herein he argued a similar view of evolution to that proposed by Lamarck. Chambers proposed a cosmic theory of transmutation, suggesting that all currently existing forms, from the solar system to all living organisms, including humans, have developed from earlier forms (Chambers 1844). He argued that life originated by spontaneous generation and that the reason behind extinction lies in flawed designs – however, a supernatural force is, according to Chambers, unnecessary. The book was received with praise, and even Charles Darwin believed that its publication may have facilitated the acceptance of his "Origin of

species," due to bringing attention to the subject of evolution and removing prejudice. Alfred Russel Wallace found the book ingenious, but in need of more evidence.

## The Theory of Evolution Through Natural Selection

The theory of evolution through natural selection was independently developed by two British naturalists – Charles Darwin and Alfred Russel Wallace. Wallace believed that every species emerged from a closely related one that had already existed. Unaware of Darwin's at the time still unpublished work, he autonomously reached similar conclusions. He wrote them in an essay, which he mailed to Darwin, asking his opinion. His effort resulted in the jointly written publication entitled *On the tendency of species to form varieties; and on the perpetuation of varieties and species by natural means of selection* (Darwin and Wallace 1858). The two scientists presented their work to the Linnean Society of London on 1 July 1858, which was organized by Joseph Dalton Hooker and Charles Lyell. At the time, Darwin had not yet written his ideas as a paper, so he read parts of his drafts of the *On the Origin of Species*, which he had already began writing, as well as parts of his correspondence with Professor Gray. Asa Gray, who Darwin met in 1839, was one of the most notable botanists of the nineteenth century. Darwin considered him a kindred spirit. Wallace's and Darwin's presentation was published as a science paper on 20 August 1858. This publication was the first revelation of their theory of evolution by natural selection. The following year, Darwin published his world-renowned book *On the Origin of Species*.

### On the Tendency of Species to Form Varieties; And on the Perpetuation of Varieties and Species by Natural Means of Selection

"Extract from an Unpublished Work on Species"  
(by Charles Darwin)

This essay contains a portion of a few chapters ("On the Variation of Organic Beings in a State of

Nature,” “On the natural means of selection,” and “On the comparison of domestic races and true species”) later published in his *On the Origin of Species*. Darwin began his essay with a reference to De Candolle’s argument of all nature being at war, “one organism with another, or with external nature” (p.46). Darwin agreed, stating, however, that this war is not a constantly ongoing one, but instead recurs at short periods (to a lesser degree) and occasionally (to a more severe degree). He further explained that it is also a result of seasonal differences in climate and food abundance. Species differ in their favoring of particular seasons, which Darwin saw as an application of Malthus’s doctrine “with a tenfold force”. He believed that mankind could double in size more quickly with more available resources; however, since animals do not have these “artificial means,” the average amount of their food is constant, but their increase will in most cases be enormous. If unexpected factors – for instance, drought – are at play, it is possible that some species will perish, while others will flourish. Darwin explained that this higher than normal increase is likely a result of more organisms surviving to the age of reproduction, and reproducing. Once the environment of the flourishing species returned to normal, the numbers would decrease. However, Darwin proposed that this decrease would still occur regardless once the environment was completely full and could not support more individuals.

Noting that most environmental changes tend to be to a fairly small degree, and therefore causing only a small change in the inhabitants, Darwin drew the attention to an example in which the population is small and isolated from others on an island, with their secluded environment undergoing a progressing change in a way that its original inhabitants would soon no longer be perfectly adapted to it. Since all individuals have to struggle for resources, and against their conspecifics, even the smallest variation of a trait that puts them at advantage could ensure success. If this variation is heritable, the offspring of the individuals carrying the variation would also have better chances. If the species continued to breed, and if the more suitable characteristics were selected for over a number of generations, it will result in a similar change

observed previously in domestic animals after the identical principle of selection.

In addition to the “natural means of selection,” Darwin recognized another similar effect – the battle of the males for the females. He believed, however, that this selection was less rigorous, as it does not require the death of the less successful individual: it just gives them fewer offspring. Darwin noted that this struggle usually occurs at times of food abundance, and it does not have an impact on traits related to food acquisition or predator avoidance. Instead, it affects secondary sexual characteristics, therefore carrying implications for intrasexual competition. These mechanisms comprise sexual selection.

#### “Abstract of a Letter from C. Darwin to Prof. Asa Gray” (by Charles Darwin)

Darwin’s essay is followed by the abstract of the letter he wrote to Professor Gray. Darwin wrote about a human-orchestrated selection of useful animals. He believed that, regardless of the degree of intention with which such selection was carried out, it was the main force behind the production of domestic animals. He explained to Gray how selection only works through the accumulation of variations and argues that humans have adapted particular races within a species for different purposes. Darwin also wrote about how the main reasons for children not completely resembling their parents are “the changed conditions of existence” (p. 51). He explained that natural selection exclusively selected for the good traits. He backed his claim by saying that any species could, given enough time, cover the entire earth, if it was not for the “check” that occurs during some part of organism’s life or during a shortly recurrent generation. He explained that this is why only a small number of organisms born each year survive long enough to propagate their species.

If a change in the environment occurs, it will likely cause a variation of the inhabitants. While some will die out, others will be exposed to the “mutual action” of a different set of inhabitants (those remaining in the population). Darwin explained to Gray his belief that the latter is of a much higher importance to each individual’s life than an environmental change. He also stated that

variation can be accumulated in any part of organism's structure, as well as useful during any part of its life. This abstract of Darwin's letter also includes an explanation of how the occurrence of new varieties, new subspecies, or even new species (i.e., speciation) will typically exterminate the previous, less well-fitted parent species. Darwin believed his letter to be very imperfect, inviting Professor Gray to use his imagination to fill up the "very wide" blanks.

Darwin and Gray continued an extensive correspondence. Gray originally did not believe in the concept of simpler species becoming more complex over time and even tried to convince Darwin that all life forms had an inherent, unmistakable design. Gray later wrote a collection of essays entitled "Darwiniana," which were published in 1888. Herein, he defended the theory of evolution, reconciling it with theology by stating that the two are not mutually exclusive. His other work focused on the morphological similarities between eastern Asian and eastern North American plants, a phenomenon that is now known as the "Asa Gray disjunction."

"On the Tendency of Varieties to Depart Indefinitely from the Original Type" (by Alfred Russel Wallace)

Wallace began his essay by stating the, at the time, generally accepted belief that the varieties, both in domesticated species and in the wildlife, are typically unstable and over time show a tendency to return to the "normal form" of the species. In his part of the paper, Wallace aimed to show that the opposite was true: His belief was that in the nature many varieties will survive, causing successive variations progressively departing from the original type, while in domesticated animals the tendency will be to return to the parent form.

Similarly to Darwin, Wallace believed that wildlife struggle to survive and reproduce, and those processes require them to fully utilize all their capacity. The main challenges the wild animals face come from environmental conditions, which affect not only the survival of individuals within a population but of entire species. Wallace further explained that large animals will not be as

abundant as small ones, and that carnivores will be less numerous than herbivores. He proposed that the prevalent view of his time that species' abundance is directly caused by their fecundity is not true. Wallace believed that entire world's population of animals is, despite the fluctuations, stationary or possibly decreasing by the influence of humans. He also suggested that every species reaches its maximum population size within just a few years of its emergence. For a population to stay stable in size, equal numbers of organisms that are born also die. If every parent pair breeds two offspring, twice the number of the new born organisms must die. In his opinion, large broods were, for this very reason, superfluous, as the majority of the offspring are likely to either become prey, or die due to environmental conditions (i.e., hunger or harsh climate). Wallace suggested that a species can increase its population size rapidly if there is a constant supply of wholesome food. Some species can tackle the problem of this condition not being met by migrating. Those that are unable to do so will, in Wallace's view, remain scarce. The organisms that die are the weakest and the least perfect.

Wallace thought that all variations have a "definite effect, however slight, on the habits or capacities" of an individual (p.57). Furthermore, if a variation offered advantages, it will over time become superior, occurring in the majority of the population. In addition, he recognized that some variations would never reach that level of prevalence. The advantageous variation will over time completely replace the original form, and the new species will be better adapted to the environment. The new form would not be able to return to its original, as the organisms carrying the original form would never be able to compete for existence. The new form would instead continue to emerge new varieties, the superior of which would again follow the same principle of replacing the currently prevalent form. Wallace referred to this as a *progression and continued divergence*. He also noted that variations that arise in aspects of no perceivable effect on the life preservation do not follow the same patterns. They can instead coexist, progressively diverge, or return to the previous form.

Unlike wild animals, domesticated animals do not have to struggle for survival and have everything provided for them. Potentially advantageous variation that occurs in these species is therefore useless and could exist without the animal's awareness. All variations emerging in domesticated animals have an equal chance of being passed on to the offspring, until humans artificially select for the preferred traits. Many of the artificially selected traits would very likely never be selected for in nature due to them being disadvantageous and thus a step towards "inferior forms" (p.60). Wallace provided the examples of these, in his opinion abnormal and irregular animals, in dog breeds and quickly-fattening pigs. If domesticated animals turn wild, they will therefore either return to the original form of the species or die out. Because the selection mechanisms worked so very differently among wildlife and domesticated animals, Wallace believed that very little can be inferred about variation in the nature from simply observing domestic animals.

In the last parts of his essay, Wallace commented on the Lamarck's theory of evolution. He believed that his hypothesis was unnecessary, as similar results are achieved by the constantly occurring variation, and those variations that ensure the most success will survive. He saw this as proof of the nature's tendency for continued progress of the varieties that successively distinguish the species from its origins, while the opposite mechanism is at play in domestic animals, which show a tendency to revert to the original form. Although these changes occur in small steps, they are continually "checked" and balanced out.

### **The Mechanism of Natural Selection, as Proposed in *On the Origin of Species***

According to Charles Darwin's conclusions published in the *On the Origin of Species*, natural selection is the inheritance of genetic traits that are more suitable to the environment. The process is, however, not driven by superiority of one organism over another in an absolute sense but by a comparative advantage that certain individuals have over their conspecifics. Natural selection is based on four principles: variation, inheritance,

population growth, and differential survival and reproduction.

#### **Variation**

Variation in traits is the precondition of natural selection. According to Darwin, organisms do not adapt to the environment – the variation in their traits is a preexisting state, and the environment simply favors organisms with certain variants of these traits. The favored traits enable the individuals who possess them to survive and reproduce in greater numbers, thus passing them on to the next generation. Over time, this process produces new species. While some characteristics can be highly variable (e.g., body size or hair color), others show very little to no variation – for example, the number of eyes or limbs among animals of the same species.

Darwin was an externalist and believed that variation was generated by environmental changes, which were its necessary prerequisite (Winther 2000). He also proposed natural selection as an external mechanism for adaptation. Darwin suggested two different ways in which the environment can cause variation: indirectly – through an altered embryonic development, or a malfunction of parents' reproductive systems, causing variation in the subsequent generation, or directly – through an action on the organism's body through the use and disuse of its organs, with the variation displayed in the same generation (Darwin 1859). In addition, Darwin offered two internal mechanisms for variation: crossing between organisms of the same species and crossing between organisms of different species, which he referred to as hybridism.

#### **Inheritance**

Inheritance is the process of genetic information being passed on from parent to offspring. Darwin's hypothetical mechanism of heredity was *pangenesis*. He presented the idea of pangenesis in his 1868 book *The Variation of Animals and Plants under Domestication* (Darwin 1868). This hypothesis was originally conceived by two ancient Greek philosophers, Hippocrates and Democritus. They postulated that an entire organism of a parent participates in heredity. Darwin's

theory was almost identical to theirs. He believed that tiny heredity particles, which he called *gemmules*, were transmitted from parent to offspring (Holterhoff 2014). These gemmules were tiny contributions from every tissue and organ of the parents, collected in their gametes, and transmitted to the offspring. They were responsible for the configuration of offspring's every tissue and organ. Since Darwin regarded gemmules as similar to plant spores and seeds, he believed it was possible for some variations to be expressed by the majority of offspring, while others could remain dormant for generations before being expressed. Darwin offered an explanation of one parent's characteristics dominating over those of the other's, considering this to be the result of that parent's gemmules being more numerous or vigorous. However, the theory failed to account for the preservation of variations through generations, as this type of inheritance would rapidly reduce the original variation to the average of the original (parents') traits (Liu 2008).

Not unlike the majority of the nineteenth-century scientists, Darwin was convinced in the idea of *blending inheritance*. This theory posited that traits from each parent were averaged and the genetic composition of offspring was a uniform, intermediate blend of their parents'. One of the problems with this theory was the lack of explanation for the propagation of beneficial mutations: according to the blending inheritance theory, favorable, new traits would be unable to spread through a population since they would be blended out in the subsequent generation.

After Darwin's 1868 publication, Francis Galton, an English statistician, conducted a series of experiments involving blood transfusion between a common lop-eared rabbit and a silver-grey rabbit. His experiments negated the pangenesis theory (Galton 1871). Darwin reacted by explaining that his theory does not state that gemmules occur are conveyed by blood. Despite this, Galton's results were the main reason why the pangenesis theory was long disregarded (Liu 2008). However, the experiments of blood transfusion carried out in the 1950s and 1970 on poultry by Sopikov, Gromov, and many other Soviet researchers yielded positive results. A possible explanation is that heritable changes are easier to detect in

poultry than in rabbits, as it can take many generations for a trait to be expressed in rabbits. Experiments using *parabiosis* – surgical joining of anatomical parts of two animals involving a blood transfusion – that Boriachok-Nizhnik (1951) conducted on Angora rabbits and Flanders rabbits resulted in the so-called vegetative hybrids of the two species, confirming that blood transfusion alters hereditary traits. Later studies suggested that another important role may be that of DNA. Experiments on ducks revealed that vegetative hybridization was possible using erythrocytic DNA (Benoit et al. 1960), and the treated parent was affected as well. It has since been shown that DNA integration is a mechanism of horizontal gene transfer through blood transfusion. A proposition that gemmules could include RNAs, circulating DNAs, and other mobile elements has been broadly accepted since the discovery of circulating DNA and RNA molecules, as well as prions in plant sap and in the blood plasma and serum of both living and deceased animals. One of the biggest critiques of the pangenesis theory is its Lamarckian hypothesis that allowed for the heredity of acquired traits. Darwin discussed the effects of use and disuse, drawing a comparison between production animals and wildlife, suggesting that some changes in traits that were commonly attributed to these processes could be results of natural selection. He related the processes that occur in the nature to artificial selection or selective breeding of domestic animals and plants, aimed towards a development of particular (desired) traits.

#### Population Growth

Darwin and Wallace believed that natural selection is dependent on a high-population growth. Darwin originally thought that a population will increase until its size is in accordance with the available resources, at which point it will become stable. However, he refined his ideas after reading an essay published in 1798 by an economist Thomas Robert Malthus entitled the "Essay on the Principle of Population." Malthus's central premise was that a growth of population will always overpower the growth of food supplies, thus creating perpetual states of struggle, hunger, and disease. Human population, is left

unrestrained, would increase beyond their means and struggle to survive. Darwin and Wallace extended this incurable struggle for survival to the evolutionary scheme, as they realized that animals and plants are likely to experience the same pressures. They proposed that the organisms that were better equipped to survive will thrive and pass those more desirable traits on to the following generation, while the organisms that were less able to cope with the inherent inequality of the environment would die out. As offspring numbers are sometimes higher than what could be supported by the local environment, they must compete. This often unconscious competition for resources will cause the mortality of less-fit offspring. Traits that ensure more successful coping with environmental challenges (e.g., harsh winters or droughts) will become more common in the next generation, which will result in an ongoing progression of the species. Darwin believed that this competition for resources will be the harshest between closely related forms sharing environmental niches, a concept he anticipated.

#### Differential Survival and Reproduction

Variation occurs among any population causing individual differences in traits. Some of the variants can enhance individual's chances of survival and reproduction. Individuals who possess traits that enable them to prevail in the struggle for resources will contribute more offspring to the next generation. If these traits are heritable, these beneficial effects will be reflected in a differential reproduction – there will be a higher proportion of organisms carrying those traits in the following generation. In some cases, the survival or reproductive advantages will be very slight. However, over many generations, they will nevertheless become predominant in the population. Even though natural selection is without a purpose, traits that carry reproductive advantages will be selected for.

### Types of Selection

There are different types of selection in regard to the effect they have on traits: *directional selection* favors a single extreme phenotype, *stabilizing*

*selection* favors an intermediate phenotype over the extremes, and a *disruptive selection* favors extreme phenotypes over an intermediate and can be a precursor of speciation. If selection acts to remove the genetic variation from the population, it is considered a *negative selection* (also known as a purifying selection). If, however, selection acts to maintain the genetic variation, it is referred to as *balancing selection*. Selection that acts to increase chances of survival is known as *viability selection* (or survival selection), while that which increases organisms reproduction rates is called *fecundity selection* (or fecundity or reproductive selection).

Types of selection that act on an individual organism are jointly referred to as *individual selection*, while *gene selection* acts on the genes. Examples of gene selection include kin selection (an evolutionary strategy that favors the reproductive success of organism's relatives, even at a cost to the organism's own survival and reproduction) and the intragenomic conflict (a situation when genes inside a genome not being transmitted by the same rules, due to a single gene causing its own transmission to the detriment of the rest of the genome). Selection that acts on groups of organisms is called *group selection*, but its mechanisms are not yet fully understood. For a group selection to take place, the trait or behavior that is being selected for needs to spread out through the entire group. Group selection has mostly been proposed in humans and eusocial species (mainly Hymenoptera). Finally, with regard to the resource that the organisms are competing for, selection be classified as sexual selection (resulting from mate competition) or ecological selection (also known as environmental or survival selection, of asexual selection), which refers to strictly ecological processes operating on species' inherited traits.

Factors that reduce survival or reproductive success within a population are called *selection pressures* or *evolutionary pressures*. If they decrease the occurrence of a trait, they are called negative selection pressures, while those that increase the proportion of a trait are called positive selection pressures. Some selection pressures are dependent on the density of a population (for examples, predators, resource availability, supply

of nutrients, or spread of pathogens and diseases), while others are not (e.g., weather conditions, changes in temperature or carbon dioxide levels, or natural disasters).

### Alternatives of the Theory of Evolution by Natural Selection

While the majority of Wallace's and Darwin's contemporaries were relatively promptly persuaded by their theory of evolution, few of them accepted natural selection as the prime driving force of evolution. The late nineteenth century brought forward a couple of alternatives to natural selection.

*Theistic evolution*, also known as *evolutionary creationism*, advocates that God guided the process of evolution. It is a middle-ground between Darwinism and religion. Supporters of theistic predetermination believed that God created the universe, as well as the natural laws within it. This view is very similar to deistic evolution (a position encompassing the belief that God created the universe but has not interfered with it since). Another form of theistic evolution proposed that God was involved in the creation process, either to start abiogenesis (spontaneous generation of life from nonliving matter) or to ensure that some mutations would have beneficial effects. Guided evolution posited that God used evolution so that humans could evolve. This view, similar to progressive creationism, comprised belief that God extensively intervened in the process of evolution, either by generating species or by modifying gene sequences, and helping beneficial mutations gain selective advantage. By the beginning of the twentieth century, theistic evolution was rarely a part of scientific discussions, but it kept a following among laymen.

*Orthogenesis*, or orthogenic (progressive, straight-line) evolution, proposed that all organisms carry an innate tendency to evolve towards a predetermined, fixed goal. This teleological hypothesis of a unilinear change of species towards perfection was supported by many eminent scientists who found proof for the argument in the seemingly constant and gradual

unidirectional change within the fossil records. The term was introduced in 1893 by Wilhelm Haacke, a German zoologist. Orthogenesis was largely discarded with the emergence of the modern synthesis, but the idea that evolution represents progress remained popular. Although this is not true, evolution does proceed in a seemingly linear way, which is in accordance with the neo-Darwinism.

*Vitalism* proposed that all living organisms are fundamentally different from the nonliving matter due to containing a non-physical element (sometimes referred to as the vital spark or energy), or regulated by different principles (Bechtel and Richardson 1998). The idea has been discussed since ancient Egypt and ancient Greece, through the Middle Ages to the nineteenth century. Among the supporters of this theory was Louis Pasteur who, after conducting several experiments, concluded that fermentation was a vital action. By mid-twentieth century, the majority of scientists had abandoned vitalism.

*Saltationism* or *mutationism* offered a faster alternative to the Darwinian concept of gradual change of natural selection, suggesting that new species emerge as a result of large mutations. This hypothesis was the basis of the mutation theory of evolution. The central premise was that species go through periods of fast mutation, possibly due to environmental stress. These mutations could produce subspecies or new species in a single generation. Modern science accepts the role of mutation in evolution, albeit only as a supplier of variation, which is then acted upon by natural selection.

*Catastrophism* is a theory that hypothesizes that the Earth was affected in the past by sudden violent events (Turney and Brown 2007). A French paleontologist Georges Cuvier proposed that the various extinctions and the patterns of faunal succession in the fossil record were caused by these large-scale natural catastrophies. He found evidence in the stratigraphic record that such catastrophic events occurred but were separated by long periods of stability. Modern biology allows for catastrophism due to the evidence of a large extinction event at the end of the Cretaceous period, which led to a loss of approximately 70% of all species (Renne et al. 2013).

*Structuralism* (biological or process structuralism) argued that evolution is not solely driven by natural selection, but that important roles are played by other mechanisms, which can in some cases completely override natural selection. Structuralism comprises several theories. Etienne Geoffroy Saint-Hillarie's *law of compensation* suggests that all animals share an ideal pattern, as evidenced by their homologous morphology. This is not a result of evolution, but a product of the law of nature. As certain parts become more developed, others are reduced in compensation. D'Arcy Wentworth Thompson's *universal laws of form* explain that the morphology of living organisms often echoes inorganic structures. Adolf Sellacher's believed that fossils were the so-called *pneu structures* and were determined by mechanical inflation rather than natural selection. Gunter P. Wagner argued that homology and biological novelty can be explained by a developmental bias of structural constraints on embryonic development. Stuart Kauffman proposed that *self-organization* plays a role alongside natural selection in population dynamics, molecular evolution, and morphogenesis. Michael Denton argued the existence of the so-called *Types* – the basic forms in nature, which were determined by the laws of form. He believed that these universal, recurring patterns were not shaped by natural selection but by the self-organizing properties of matter and the laws of nature. Stephen J. Gould and Richard Lewontin suggested that many biological features, which they compared to architectural *spandrels*, do not always arise as direct results of adaptation but can be consequences of evolutionary changes, or even exaptations. Brian Goodwin proposed that natural patterns can be created by spatial oscillations of chemical signals, similar to the way in which morphogenetic fields operate (Webster and Goodwin 1996). Extreme structuralists G.B. Muller and S.A. Newman held the view that diversifications of species are dictated by the physical laws of structure. They believed that a relatively unconstrained, “pre-Mendelian” phase in animal evolution existed in the early stages of the multicellular life, suggesting possible explanations of how organisms evolved genetic mechanisms (Newman et al. 2003).

The most popular alternative to Darwin's theory at the end of the nineteenth century was *neo-Lamarckism*. In addition to Lamarck's original ideas, neo-Lamarckism included a proposition that environment can directly alter organic structures. This was used as an explanation to why organisms are adapted to their environments. However, the largest flaw of this theory was the complete lack of solid evidence suggesting the inheritance of acquired traits. As the genetics field progressively developed, neo-Lamarckism began to lose support.

## The Modern Synthesis (the Neo-Darwinism)

The Modern Synthesis is the modern theory of evolution that arose in the 1930s and 1940s from the merger of Darwinian theory of evolution and Mendelian genetics. It advocates the genetic basis of evolution, describing it as a change in the allele frequency within a population. The theory is also based in the population genetics, and the work of such as Ronald Aylmer Fisher, an English biologist and statistician, Sewall Wright, an American geneticist, or John Burdon Sanderson Haldane, an English-born Indian biologist and biostatistician.

### Central Contributors of the Modern Synthesis

Several distinguished scientists contributed to the development of the Modern Synthesis. Theodosius Grygorovych Dobzhansky, a Ukrainian-American geneticist and evolutionary biologist, greatly influenced the development of the Modern Synthesis with his 1937 publication *Genetics and the Origin of Species*. He proposed that evolution is a change in the allele frequency within a gene pool, explaining that natural selection works through mutation (Dobzhansky 1937).

Ernst Walter Mayr was an evolutionary biologist and a taxonomist. His main contribution to the Modern Synthesis theory came from his re-definition of the term species so as to include a group of not only morphologically similar individuals but those who can breed only among themselves. He also developed a theory of peripatric speciation – explaining the speciation that

arises from an isolated peripheral population (Mayr 1954), which was the basis of the theory of *punctuated equilibrium*, developed by Stephen Jay Gould and Niles Eldredge (Eldredge and Gould 1972). This theory proposed that most changes that occurred in the evolutionary history happened very rapidly, in short bursts of branching speciation (i.e., cladogenesis) typically lasting less than 100,000 years. After a species has appeared in the fossil record, it will show very little evolutionary change for the rest of its geological history, which they called *stasis*. The opposite idea, proposing that evolution typically occurs smoothly and uniformly, by the steady gradual change of entire lineages is called phyletic gradualism.

George Gaylord Simpson, an American paleontologist, integrated paleontology with genetics and natural selection. He developed methods of analysis of the rates of evolution through time and showed their variability. Furthermore, he introduced the term of *quantum evolution* to explain sudden emergences of lineages (Simpson 1944). He suggested that microevolution of population genetics offered an adequate explanation of the macroevolution patterns observable by paleontology. In his book *Tempo and Mode in Evolution*, published in 1944, he defined *tempo* as the evolutionary acceleration and deceleration, the evidence of which could both be found in the fossil record. Simpson described *mode* as the pattern of evolution, more encompassing than evolutionary rates that were its basic factor. Simpson noted that Gould's and Eldredge's punctuated equilibrium theory is a reiteration of his idea of quantum evolution.

George Ledyard Stebbins Jr. was an American botanist and geneticist, and one of the leading evolutionary biologists of the twentieth century. In his work he combined genetics and Darwin's theory of evolution by natural selection to describing the speciation of plant species (Stebbins 1950). He was the first to discuss natural selection in plants.

Julian Huxley, a British evolutionary biologist and T.H. Huxley's grandson, coined the terms *modern synthesis* and *evolutionary synthesis*. In his 1942 publication *Evolution: The Modern*

*Synthesis*, he integrated Darwin's theory of evolution with Mendelian genetics and population genetics. He believed that different groups will differ in the nature of their evolution, depending on the various factors, for example their reproductive strategies and genetic material (Huxley 1942). He published numerous books in collaboration with many of his eminent peers and worked on the popularization of science and evolutionary biology through many public appearances on television and the radio.

Bernhard Rensch, a German evolutionary biologist, popularized the Modern Synthesis in Germany. He studied environmental impacts on the evolution of geographically isolated species. Moreover, in his book *Evolution above the species level*, published in 1947, he aimed to prove that the major evolutionary trends and the formation of species and races are governed by the same factors (Rensch 1960).

### Differences Between the Modern Synthesis and Darwin's Theory

According to the premises of the Modern Synthesis, natural selection remains a driving force of evolution, but its power is joined with that of gene flow (the transfer of alleles or genes between populations, which happens as a result of immigration or emigration of individuals), genetic drift (the random change in allele frequency in a population caused by random sampling), and mutation (a change in the DNA sequence, which can involve deletions, duplications, insertions, or inversions (translocations)). The Modern Synthesis provides an explanation of how genetic variation (i.e., variation in the alleles) persists. As Darwin supported the theory of blending inheritance, he struggled to explain this. Mendelian inheritance gave a new perspective for tackling this issue. Gregor Mendel was an Austrian scientist and a monk who, after experimenting with pea plants, showed that genes play a role in the traits of an organism, and that those traits can be statistically predicted using the knowledge of genetic makeup of organism's parents. According to Mendel's laws, alleles (i.e., DNA segments of genes) do not merge and blend out. In reference to traits, Mendel created the terms "dominant,"

describing the allele whose effect on organism's phenotype masks the contribution of the other allele, and "recessive," describing the allele whose effect is masked by that of the other allele. While Mendel's work is the cornerstone of modern genetics, his views were not broadly accepted or known until the beginning of the twentieth century. Mendel was aware of Darwin's work, which he studied in great detail. There are a few indications that Darwin could have been familiar with Mendel's work – portions of Mendel's publications and references to them made by other authors were included in books later found in Darwin's library and were thus likely available to him. Mendel sent a copy of his 1865 paper "Versuche uber Pflanzen-Hybriden" ("Experiments in Plant Hybridization") to 40 of the most renowned nineteenth-century scientists, but it is not known for certain whether or not Darwin was one of the 40 scientists who received a copy, or whether he read it.

According to Mendelian genetics, genetic variation can occur both within populations and among them. It allows the natural selection to decrease or increase the frequency of alleles that already exist. Genetic variation arises from the formation of new alleles, alteration of the number or position of genes, rapid reproduction, and recombination between chromatids of homologous chromosomes during meiosis (a process also known as the *crossing over*) in sexually reproducing species. Some genetic variations that arise can have a neutral effect, in which case they will be neither selected for or against, and are likely to remain in the population. In addition to the variation within a population, species can also exhibit geographic variation – variation in the genotype of geographically separated populations. These distinctions can arise either due to a separation by environmental barriers or because of the different selection pressures caused by different environments. When a change in an environment generates new available resources, creates new challenges or opens new niches, adaptive radiation (also known as divergent evolution) can take place. It is a rapid diversification of species into a multitude of new forms. One of the most famous examples of an adaptive

radiation is the so-called *Darwin's finches*. Occupying fragmented landscape of the Galapagos islands, they have diversified in their ecology and morphology – most notably the size and shape of their beaks, which provided Darwin with evidence for his theory of evolution.

## The Second Synthesis: Evolutionary Developmental Biology

As molecular genetics continue to advance, a new field of *evolutionary developmental biology* started to emerge. The research of this field, informally referred to as "evo-devo," aims to explain evolution in terms of the genetic regulatory network – a collection of molecular regulators governing the gene expression of mRNA and proteins, through the interaction with each other and other cell substances. They have a central role in the creation of body structures (morphogenesis). The central premise of the field is the existence of a subset of genes that control the organism's embryonic development, called the *evo-devo gene toolkit*. These genes are conserved among phyla and thought to date back to the last common ancestor of all bilaterally symmetric animals (animals that have mirror symmetry in the sagittal plane vertically dividing their bodies into left and right halves, with each side comprising one of each sense organ and limb pair). These genes also tend to convergently (independently) evolve the same function. According to evolutionary developmental biology, variation does not arise from mutation of gene sequences but from mutation-driven changes in gene regulation. Variation can thus result from a toolkit gene being expressed in a different pattern (i.e., under-expressed or non-expressed) or from it acquiring a new function.

Darwin's theory also left a mark on the development of cell-biology and molecular-biology. The so-called *cellular Darwinism* proposes that stochasticity (or random variation) at the molecular level generates diversity in cell types, whereas cell interactions import a characteristic order on the developing embryo (Kupiec 2010). It is based on the work of Wilhelm Roux, a German

zoologist and embryologist, who believed that a Darwinian competition occurs at all levels of organisms, from molecules to organs, during embryonic development.

## Social Darwinism

Darwin's theory of evolution by natural selection had implications for the social sciences. The term *social Darwinism* refers to theories that apply his concepts of natural evolution to human society. Social Darwinism emerged in the late 1880s and was first described by Oscar Schmidt, but the term was used fairly rarely until 1944 when Richard Hofstadter, an American historian, published a book entitled *Social Darwinism in American Thought*. Social evolution and cultural evolution hypotheses were common during the Enlightenment, as well as seventeenth-century thinkers, but social Darwinism differs from the other theories of social change as the ideas are drawn from biology. In addition to believing that humans also struggle for resources and that advantageous physical and psychological traits are accumulated over time, Darwin proposed that social instincts also evolve through natural selection, which strengthens societies in which they occur (Darwin 1871).

## Universal Darwinism

*Universal or generalized Darwinism*, also known as the *Darwinian metaphysics* or the *universal selection theory*, comprises a variety of extensions of Darwin's original theory of evolution, aiming to explain evolution in an array of other disciplines. These extensions can be grouped depending on whether they focus on the biological implications of evolution (i.e., psychology or medicine) or whether they discuss the evolution of entities other than genes (i.e., computer science). Gene-based extensions include evolutionary psychology, evolutionary aesthetics, evolutionary anthropology, evolutionary musicology, sociobiology, human behavioral ecology, evolutionary

epistemology, evolutionary medicine, Darwinian literary studies, Darwinian happiness, molecular evolution, evolutionary linguistics, and other. Examples of non-gene-based extensions include quantum Darwinism, cosmological natural selection, memetics, cultural selection theory, evolutionary economics, evolutionary ethics, evolutionary art, evolutionary music, genetic algorithms, dual inheritance theory, and neural Darwinism.

## Naturalistic Stimuli

Hakan Çetinkaya

Department of Psychology, Faculty of Languages, History and Geography, Ankara University, Ankara, Turkey

## Synonyms

Biologically significant stimuli; Ecological stimuli; Evolutionarily relevant stimuli; Functionally relevant

## Definition

Naturalistic stimuli are cues that reliably precede biologically significant events (e.g., an unconditioned stimulus, US) that animals have encountered recurrently in their evolutionary histories. Thus, a natural precursor of a US is regarded as

a naturalistic stimulus given its inherent relationship with the US.

## Introduction

From the traditional associative perspective, conditioned responses should develop regardless of the preexisting relations between the conditioned stimulus (CS) and unconditioned stimulus (US). Accordingly, any stimulus could be paired with any US as effectively as any other stimulus to produce conditioned responding. This view calls forth the idea that prior to conditioning the CS, by definition, is “neutral” and therefore the CS is arbitrary with respect to its potential to elicit a CR after being paired with a US. As Pavlov once assumed, any cue an animal could sense could be used as a conditioned stimulus for any response (Lakoff and Johnson 1999). Similarly, Skinner (1938) maintained that any arbitrary associative link could be formed between a response and the outcome. They assumed that the same laws of learning operated in all species and learning was about making connections between arbitrarily chosen stimuli and responses. This purely mechanistic-associative view has changed as behaviorist principles have undergone significant revision, particularly in light of findings from functional perspectives on animal learning (Domjan 2000). Curiously, as one of the fathers of behaviorism, Edward Thorndike himself believed that stimuli were not potentially equal in their effects on behavior and introduced the notion of “belongingness” in his formulation of the “Law of Effect.”

In contrast with traditional, general process approaches to learning, functional perspectives on conditioning have examined the inherent relationships between stimuli in naturalistic settings. According to functional views, learning provides organisms with an effective way of dealing with the particular kinds of problems they have recurrently encountered in their environments; hence learning mechanisms are specialized. According to this view, learning cannot be accounted for by a single, general process, but rather by many processes that relate to specific problems. Learning

mechanisms are thus been seen as responses by ecological opportunities and challenges, and therefore influenced by natural selection. Given the biological significance of the US, a CS would not likely be something arbitrary under natural circumstances. According to Domjan and Krause (2017) “. . . stimuli and responses that are a part of that ecology will activate the learning process more effectively” (p. 10). After all, arbitrary stimuli do not occur often enough with ecologically relevant USs to result in their becoming CSs. For this reason, it has been hypothesized that learning is more likely if the CS has a preexisting relation to the US (Domjan et al. 2004).

Ecologically relevant cues are readily associated with their resulting counterparts. For example, rats were able to associate audiovisual cues with a foot shock, but not so with illness; moreover, they were able to associate taste cues with illness, but not so with the foot shock (Garcia and Köelling 1966). Similarly, Foree and LoLordo (1973) found that pigeons predominantly use auditory cues as discriminative stimuli for avoidance behavior as opposed to visual cues. The functional perspective provides us with a glimpse into the ultimate causation of learning, in addition to its proximate underpinnings. Cole et al. (1982) elegantly showed how ecological relevance of stimuli affects conditioning. Hummingbirds were provided with two artificial flowers: one containing food and the other empty. The experiment consisted of two types of learning conditions. In the win-stay condition, subjects were trained to search for food in the same flower that they had received food in during a preliminary phase of the trial. In the win-shift condition, the subjects were required to visit an artificial flower at a location that differed from the preliminary trial in order to receive reinforcement. Results showed that the birds learned the win-shift condition significantly faster than the win-stay condition. More interestingly, opposite results were obtained when they used water as the biologically important stimulus. This time, birds tended to learn the win-stay strategy more readily than the win-shift strategy. Although these findings are highly puzzling from the traditional associative perspective, they make sense from the functional

view of learning and memory, especially given the relative constancy of the food and water sources in the birds' ecological niche. This study presents an example of the inherent relationship between ecological variables. This idea is quite compatible with the Behavior Systems approach formulated by Timberlake and his colleagues (1989).

According to the Behavior Systems approach, behavior is the product of functional systems (e.g., feeding, reproduction, predatory defense), and behavioral outcomes of conditioning are shaped by these functional systems. Each of those functional systems has evolved to achieve some important biological goal. For a food deprived animal, a piece of food is a desired US, and it activates an appetitive feeding behavior system which generally includes approach responses, while an unpleasant US such as presentation of a brief foot shock activates a defense behavior system which generally includes aversive responses. Thus, in a Pavlovian conditioning procedure a conditioned stimulus (CS) is integrated into the behavior system that is activated by the US. A brief foot shock causes rats to jump in the experimental cage. However, contrary to the stimulus substitution approaches to associative learning, the cues (punctate or contextual CSs) preceding the shock (US) elicit a freezing response as the CR (e.g., Bolles and Collier 1976; Fanselow 1980). The signaling CS gains conditioned properties and becomes a part of the defense behavior system of the animal. Therefore, the nature of the resultant conditioned response is determined by the behavior system relevant to the US involved. For that reason, the CR is not jumping, but rather freezing. The ease of learning a particular task depends on the extent to which the task is consistent with the behavior system that is activated by that conditioning procedure. In natural circumstances, ecological CSs that are already parts of the relevant behavior system reliably precede the occurrence of USs.

On the one hand, traditional mechanistic associative accounts of conditioning claim indifference between arbitrary and naturalistic stimuli, and on the other hand functionalist approaches to learning argue for the importance of naturalistic learning paradigms. Michael

Domjan and his colleagues (2004) have recently proposed an overarching approach that differs from general process learning perspectives.

More than 30 years ago, Domjan and Galef (1983, p. 160) stated, "carefully designed comparative investigations of learning can add a biological dimension and help integrate the study of learning with behavioral ecology and phylogeny without rejecting the general process tradition." Although there is strong agreement with the general idea that the primary function of the CR is to help the organism respond to the US more effectively, actual tests comparing naturalistic and arbitrary stimuli are relatively rare. Öhman and Mineka (2001) demonstrated that fear was acquired more readily to ecologically relevant cues, such as the sight of a snake, than to ecologically irrelevant cues, such as the sight of flowers. Over the years, Domjan and his colleagues have been able to build the empirical and theoretical bridge between the general process and naturalistic views of learning. A tenet to this approach is that the study of ecologically relevant stimuli will help us better understand how learning interacts with the preexisting organization of behavior. Domjan (1994) attempted to integrate stimulus and response factors into a general theory of learning and was able to test this attempt in an animal model of sexual conditioning in Japanese quail. This research program also provided insight into the ecological relevance of learning, since it requires comparing stimuli used during testing with those encountered in natural circumstances.

In the sexual behavior system of Japanese quail (*Coturnix coturnix japonica*), conditioned responses to a naturalistic CS (e.g., head-neck model of a female), compared to an arbitrary stimulus, were substantially enhanced if it was paired with a US (live female). The naturalistic CS was resistant to the blocking effect and the response attenuating effects of extinction procedures. Conditioned responding developed more rapidly toward the naturalistic CS, and a greater range of conditioned responses came to be elicited. The presence of naturalistically relevant features in a CS object increased the effectiveness of that CS in producing second-order

conditioning. Learning with the naturalistic CS was not easily disrupted by increasing the CS-US interval, and vigorous responding to naturalistic CS was observed, even with very low I/T ratios (for review see Domjan 2008).

It is worth mentioning some interesting observations and implications of the functionalist approach to conditioning. First, it establishes a continuum consisting of entirely unrelated, purely arbitrary stimuli at one end, and US-related, highly naturalistic stimuli at the other. Second, it nicely accommodates Timberlake's Behavioral Systems approach, the Biological Constraints View, the concept of Preparedness, and Naturalistic Learning paradigms. Third, it does not exclude the general process learning perspective but does challenge some basic tenets. Finally, the functionalist perspective is heuristically valuable, is supported on both empirical and theoretical bases, has supportive evidence from behavioral systems such as sexual and aversive conditioning, and it stimulates future studies integrating ecological analyses into traditional learning approaches.

In conclusion, traditional views of conditioning generally underestimated the significance of naturalistic stimuli on animal learning and conditioning. Implicitly or explicitly, they postulated that the CS has no inherent relation to the US prior to conditioning. Functional perspectives, on the other hand, actively acknowledge the role of preexisting relationships between stimuli in naturalistic settings. Thus, learning about naturalistic cues preceding a biologically important event would occur more readily and produce different conditioning phenomena. This idea has been supported by several lines of work that has added to our understanding about the interaction between the conditioned and unconditioned organization of behavior.

## Synonyms

Nature: [Character](#); [Condition of birth](#); [Quality](#); [World](#)

Nurture: [Bring up](#); [Nourishment](#)

## Definition

The word “Nature” is originated from the Latin word *nātūra*, which means conditions of birth, quality, character, natural order, world, etc. In other words, nature is the material world that surrounds individuals and may exist independently, even if there is no human activity. In another aspect, nature also refers to the specific features, characters, or qualities of something or someone which is inherited and transferred from one generation to another generation. In concern to the human being, nature is the genetics that determines one’s behavior like personality traits and abilities.

On the other hand, the word “Nurture” is originated from the Latin word *nutrire*, which means to nourish. The surrounding environment of a person, his upbringing, and life experiences

determine his behavior in a certain way. In other words, nurture can be defined as the one who nourishes, giving food, or helps to develop someone or something. For example, a bird feeding her baby is the nurture of the baby bird.

## Introduction

Diversification leads to uniqueness or individuality. Although being the same in all aspects, every individual on the globe is yet different from one another. These kinds of differences in race, intelligence, behavior, etc. are governed by certain factors that may include the one we might be focusing on. In a huge, vast, and diversified population of life on earth, the exactness or commonness has no more significant role to play. From the past few decades, the workers are trying hard to reveal the reasons behind such diversifications in behaviors. One of the most common connections revealed through several studies done in the past includes those between the surrounding environments with that of the behaviors. The outer space or the place of harbor plays a major role in shaping up the character of an individual or lining of their behaviors. Many times providing the same environment to different groups of people shows different behavioral patterns. The 50% of one’s actions or any act of intelligence or related to learning and cognition depends upon the genetic material that we receive from our parents (Plomin 2018).

The commonly used term for all types of human behaviors is their “nature.” It may be referred to as the genes that are pre-wired and influences the innate characters irrespective of their place of birth. Nurture, on the other hand, is related to the learned aspects of nature, i.e., influences of exposures of the surrounding environment directly or indirectly on the behavior of an individual. The theory of nature versus nurture initially came into the light in 1869 and the psychologist Sir Francis Galton was credited to use the term for the first time in history (Bynum 2002). The topic of nature versus nurture becomes the cause of debate among scientists, doctors, behaviorists, and many others. So this is very

clear that it is going to be difficult to understand the relation of nature and nurture with human behavior and personality, correlation and/or differences between nature and nurture, etc. Prior to understanding the topic of nature versus nurture, we have to know what human behavior is. Various research on mirror neurons, automatic imitation, mimicry, etc. is explaining human behavior as fundamental behavior which has a very important role for human beings to understand who they are and for what they born in this world, their responsibility toward the community. The studies are explaining fundamental human behavior as an immediate, uncertain, and difficult to control, which should be adjusted according to the objectives of our society (Lakin and Chartrand 2003; Corballis 2010; Heyes 2011).

An individual person is a unit of society; so to adjust us into a society, it is important to understand that what individuality is and the factors affecting it. The individuality refers to the way a human behaves differently in different situations. The diversity of single individuals depends upon many factors involving some common ones such as the surrounding environment, genetic factors, parenting styles, inborn intelligence, etc. These have some or the other effects on a newborn child during its growth phase. The growth phase of a child is considered as the most crucial phase of its development and sometimes future consequences are also decided based on one's growth.

In a book titled as "The Developing Genome" written by psychologist David S. Moore, it has been explained that in this fast-growing world with a burgeoning population it is important to know that genes are playing a crucial role and what these are doing is somehow influenced by the changeable environment in which these genes are sustained. Expression of genes can also get affected by some other factors like one's nutrition, stress, toxin exposure, etc. The above explanation indicates that genes (nature) and the surrounding environment (nurture), both are playing an important role in the development of human beings and are correlated with each other. But in another book "Gene and Behaviour" by Michael Rutter, it has been summarized that there is not a single factor or gene that is responsible for the sort of behavior

a human shows, rather it is a multifactorial existence of behavioral genetics, i.e., polygeny influence the pleiotropy, particularly in the area of psychiatric disorders. The occurrence of many neurodegenerative disorders is influenced by the genes irrespective of the environmental conditions provided. The primary environmental or genetic disorder is one that is independent of any of the other factors. If the disorder is of genetic type, the outer surroundings or the social factor doesn't provide any impact on the disease and vice versa (Simon et al. 2002).

From the above discussion, this is very clear that the topic nature versus nurture will be difficult to explain, which is more important as either nature or nurture, both are interrelated or independent to influence one's behavior and many more. Nature versus nurture is the topic of argument for several decades which concerns the relative contribution of human biology and behavior such as personality development, intellectual capacity, cognitive trait, scientific temperament, mental illness, and biopsychology. According to researchers, nature is the human behavior which evolves from heredity, gene, and other factors (Levitt 2013). On the other hand, nurture is the method by which behavior can develop. Nurture is controlled by external factors (Plomin et al. 2014). For example, the physical character is determined by one's gene with respect to their birth and growth, but nurture refers to one's childhood or how they were taught. So nature is fixed and cannot change but nurture is a kind of learned behavior that is changeable.

The debate on nature versus nurture is based on the discussion between one's learned and acquired behavior. There is a disputing explanation about behavior. According to some scientists, behavior is evolved from own gene or nature, meanwhile some other scientists are there who believe that behavior is the result of the environment or nurture. It is assumed that living mechanisms and thoughts of a person depend on their nature and nurture, but actually it is not clear how much of human traits are influenced by nature and nurture. According to Mullen (2006), unique individual feature is determined by unique gene and genomic or biological feature while nature presumably

refers to one's behavior in relation to his social and physical environment both. So here upon, as the theory of human behavior, nature describes cognitive trait, personality aggressiveness, and intelligence. Human behavior varies from person to person depending upon the genetic make-up of a person. Thought of a person and his vision around him or his opinion about the particular situation is determined by his own biological make-up (Ekelund et al. 1999). Scientists found that human traits such as hair color are acquired from parents. Further, they elaborate the point of contents that an individual's personality, sexual orientation, intelligence, and aggression are decided by their genes (Bleidorn et al. 2010). The personality of an individual is different from child to adult. But the question arises that what nature is, either personality of human being, his intelligence, or the natural world around humans. On this, there are many opinions of different scientists. To know what exactly nature is all about, we have to understand more about nature.

## Nature

As already mentioned, nature refers to the pre-wired information stored in the genes inside the cell and is hereditary, i.e., it gets passed on to their successive generations. Besides this, there exist several other aspects to define "nature." Many workers define nature according to their field of interests. The broad aspect of defining it has its own uniqueness and diversification.

According to Psychology, nature is the personality and physical appearance of a person which results from the specific genes he has and their characters which are inherited generation by generation (Cherry 2017).

According to Ecology, it refers to all forms of life on earth that have their origin ranging from subatomic to cosmic. Also, the natural environment includes all those areas that have not been altered by humans or those that persisted despite human interventions.

The above-mentioned aspects are interrelated as both are including humans as an entity that is being affected. Both the genetic factors as well as

the surrounding environment influence the development of behavior in an individual human being.

Certain theories support the development of an individual depends entirely on nature regardless of the environment provided. This was supported strongly by two great philosophers Plato and Descartes. They also believed that inherited characters decide almost all kinds of behaviors that an individual shows.

According to the Language Acquisition Device (LAD) theory of Chomsky, the capacity of children to learn and speak a language is governed by their instinctive mental ability obtained from their parents.

The biopsychology researchers supports nature's view of human eugenics by conducting experiments related to the working of neurotransmitters in shaping one's behavioral patterns.

If the theories mentioned above explain what nature is, then the question is what the nurture is and how it is different from nature.

## Nurture

Nurture refers to the surrounding culture, childhood experiences, and other social relationships that played a significant role in building up the behavioral characters of an individual. The impact of surrounding one's personality development is commonly referred to as a nurturing pattern.

Supporting statements giving critical place to nurture in defining one's behavior includes John Locke's belief that the mind begins as a blank state, i.e., the knowledge is acquired by the experiences of life.

According to a theory by John B. Watson, each individual has the ability of becoming whatever they want if proper conditioning is done regardless of the genes obtained from their parents.

The behavior of a person is highly influenced by parenting styles as well as the experiences that the one has gone through. For example, the manners of thanking and regretting by saying "thank you" and "sorry" is learned by the children from their surrounding only. This environmental surrounding supports the view that behaviors are governed by conditioning, i.e., nurture.

A more interesting theory in Psychology by Bandura (1977), i.e., Social Learning Theory, extensively provides a strong view in support of nurture's involvement in shaping the behavior of an individual. He conducted the "Bobo-doll experiment" with one most critical conclusions that the aggressive behavior in children is acquired by their surrounding environment observations (McLeod 2018).

The area of social psychology supports the nurture side view of the human behavior development enclosing crucial entity, i.e., peer pressure.

One of the common forms of human disorders is depression which is likely to be caused in almost all parts of the globe regardless of the environmental conditions. The contribution of such a common disorder is at least 38%, which is thought to be caused due to genetic factors or heritability (Kendler et al. 2006).

Nature accounts for about 30% and 60% of the total physiological traits of human behavior and the rest 40–70% depends upon the surrounding in which the person harbors, i.e., the higher percentage favors the nongenetic view of human behavioral development patterns (Plomin et al. 2013). It seems to be difficult to evaluate the argument about nature versus nurture that which is more important but this is quite clear that nature defined the gene and nurture refers to the surrounding environment.

## Nature–Nurture: Gene and Environment

The interaction between genes and the environment is all about phenotype. Phenotype is the physical appearance of the trait in real life and experimental condition. Phenotype is measured by questionnaire, test, and interview.

### Gene

Gene is the factor that represents the unit of inheritance. An allele is the alternative form of the gene that is present at the same locus on the chromosome. The position of a gene on the chromosome is the locus of a gene. The alleles are represented by "R" or "r" simplest system for a locus. A genotype is the set of chromosomes of an allele

for an individual. At a single locus, genotype may be represented as RR, Rr, or rr and for multiple-locus it may be symbolized by RRRY, RRYy, RRyy, RrYY, RrYy, Rryy, rrYY, rrYy, or rryy in case of two loci. A similar allele at corresponding loci on the homologous chromosome is termed as homozygosity while heterozygosity refers to different alleles at corresponding loci on the chromosome.

There are two kinds of genetic effects distinguished by Geneticists as an additive and nonadditive genetic effect (Neale and Cardon 1992). An additive effect is the effect of different genes that add together in their effect on trait while nonadditive is the genetic effect that does not add together in their effect on the trait. Nonadditive are dominance and epistasis. Intercommunication between two alleles at the same locus on the chromosome represents dominance. On the other hand, epistasis represents the intercommunication between two alleles at a different locus on the chromosome. The variety of epistatic interactions in animals depends on the number and effect the interacting loci have shown (Montooth et al. 2003; Andresson and Georges 2004; Williams et al. 2004). However, epistatic effect in human studies is not yet identified because of the absence of specific loci (Purcell and Sham 2004). When looking at outcomes for twins studies, it is realized that the epistatic effect cannot impure the heritability.

Heritability is the difference in a particular population at a particular time due to the genetic difference of an individual. It is defined as broad sense as well as narrow-sense heritability. Broad sense heritability is additive and narrow-sense heritability is nonadditive (dominance). Most twin's study is taken in a narrow-sense heritability because they show resemblance of offspring to their parents (Plomin et al. 2000). The concept of heritability is to observe differences among genetic factors of the individual.

### Environment

The environment is the nongenetic biological and noninherited factor and is influenced by other than inherited factors (Plomin et al. 2000). It is influenced by the shared and nonshared

environmental factors. Factors that are shared between the members of the twin pair are shared environmental factors, for example, a twin living in the same place and sharing their problems and hobbies. The factors which are not shared between the individuals of twin pair are nonshared environmental factors, for example, having different friends living in different places and having different interest. The theoretical and empirical tradition concludes that psychological behavior is influenced by shared rather than nonshared environmental factors, while according to behavioral genetic research, psychological traits are influenced by nonshared environmental factors rather than shared environmental influences (Plomin and Daniels 1987). It is concluded that phenotype is influenced by genetic factors, shared, and nonshared environment. As genetic factors and shared environmental factors involved in the same family are more similar to each other and different from other families influencing the phenotype. The nonshared environmental factor is the difference between the same family influencing phenotype.

According to the above studies, it is not necessary to be similar in personality, cognitive abilities, or schizophrenia-like disease even if two persons are physically similar. Physical similarity and personality are totally independent of each other (Kendler et al. 1993). The above studies conclude that genetic and environmental factors influence one's phenotype independently. But some of the studied cases didn't follow the above conclusion, so it is also important to understand the correlation between nature and nurture.

## Interrelations between Nature and Nurture

Researchers working in the field of science with specific approaches to reveal the interrelationship of nature with that of nurture have conducted several studies. The most common studies are the Twin and the Adoption study (Plomin et al. 2001). In this study, the differences between the two groups were taken into considerations. One group comprises of twins whose genetic materials

resemble one another. The other group consists of those whose genetic profile doesn't resemble at all. After providing the same environmental conditions, the changes in the behavior of each group were analyzed. Genetic researches have shown that heredity influence mental illness, personality, cognitive disabilities, etc. (Plomin and Asbury 2005). These two studies are the examples of a broader class of methods that are commonly used for the observation of nature–nurture relationship and are coming under the area of science known as “quantitative genetics,” the scientific discipline which analyses the similarities among persons depending on the percentage of biological interrelation between them. Quantitative genetics work on behalf of the number which is varying from 0 to 1 and called a heritability coefficient. The heritability coefficient evaluates the differences between two individuals based on the differences between their genes. These studies can be applied to siblings and half-siblings, cousins, and twins who got separated at the time of birth and grown separately (Plomin et al. 2012). The twin study observing the nature and nurture by the means of comparison of similarities between the two kinds of twins as monozygotic (MZ) also known as “identical twins” and the dizygotic twins (DZ) also called “fraternal twins.” Another study known as the Adoption study explains some interesting things like if a child of tall parents will be adopted by the family with short height then this is possible that the child will be taller or if the language of the biological parents of an adopted child was not similar to that of his present parents, possibly he speaks in the language of his parents with whom he lives for several years after adoption rather than his biological parents. The Twin and Adoption study concluded that both the genes and the surrounding environment affect the behavior of a person but the more weightage has been given to the genes rather than the environmental surroundings. But two drawbacks are there with the study as it fails to explain the adoption theory and if the theory can be applied to individuals rather than groups. But later in one of the great books of an American psychologist and geneticist Robert Plomin named “Blueprint: How DNA Makes Us Who We Are,” it has been

explained that these studies are not necessarily related to individual differences. He explained it with the help of average differences among a group of individuals. According to Plomin, this might be possible that heritability of a trait is high individually but if the average differences are higher in an ethnic group or a specific gender, then this can be possible only because of environmental factors.

The differences in the genetic material are consistent and are the source of all kinds of psychological individuality. DNA is the blueprint of who we are, i.e., our behavior depends on the genes more than the surroundings. The encoded genes are responsible for the kind of action we perform up to some extent. But it's not necessarily mandatory that only the genes take the responsibility of all behaviors. The behavioral differences are observed when the exposure of an individual is studied at different surroundings. For example, there is a perception about the IQ that children born in highly educated families are more educated than the children born in comparatively less educated families. According to research, it was found that if the family income play as an environmental factor, then in about 70–75% cases ability (which measured as IQ) affects the educational emoluments which can be termed as genetic effects. Although the study remains complicated to find which factor is dominant, either nature or nurture as it fails in adoption theory, two points come into the light. One is that ability to avail facilities can play an important factor in educational achievement by children only to a certain extent. But the inheritance is more responsible for educational achievement by the children (Plug and Vijverberg 2003). The quality of behavior alters with factors such as parenting, education, life-shaping events, friend goals, area of living, quality of life living, etc. The more time one is exposed to the mentioned attributes, the more effective it shows. It might be supposed that human being has a greater capacity to achieve many things than any other species because they have greater sense and IQ than others. The developed qualities and life goals of a person are partially determined by his societal systems in which he is assigned for development. This social

system provides a competitive atmosphere, strong efficacy, opportunity, platform, aidful resources, etc. for the self-realization of their wishes (Bandura 1999). The above explanation is giving direction also toward the importance of nurture (environment).

The differences between nature and nurture do not have a clear picture and understanding but epigenetic mechanisms have shown that permanent changes or mutagenesis can be caused due to environmental exposures. Also, the effect of mutagens is long lasting and is at the level of genes. According to Randy Jirtle (an epigenomist), the debate on “nature versus nurture” is quite irrelevant because it was found that both of the forces interact in such a specific way that can switch the gene behavior (Miller nad Jones 2014). The best example of the above explanation is Darwin's theory of evolution by natural selection which is taking the side of survival of the fittest as the theory states that the organisms which are congruent with the surrounding environment will survive and reproduce. On the other hand, the organisms which are comparatively less compatible with their environment will die off. Giraffe's long neck is the best example as they evolved such an uncommon and helpful trait for reaching toward the leaves on height for their nourishment and survival.

To understand more about the interrelation between nature and nurture, a group of researchers found that the ability of understanding music is linked to a single gene but this cannot work alone. For a child to become a master of his field, the perfect training of that interest is also required the most. These views support the interactive theories of nature with that of nurture in deciding the future actions of a child. Another interesting example of the interaction between the two can be analyzed in families with healthier parents having undernourished children. It's not only the genes that are responsible for the physique of a child, the nourishment also plays a central role in ruling it (Fig. 1).

Human behavioral development nowadays doesn't have a monotonous view, i.e., either nature or nurture, rather it shows a dichotomous view focusing on both the aspects. A new research

**Nature Versus Nurture, Fig. 1** Interrelation between nature and nurture

area influencing human behavior has come up, which lies somewhat in between the genes and the environment or includes interactions of both of them. The area is popularly known as “Epigenetics” (Griffiths and Stotz 2013; Jablonka 2016). Human behavior is referred to as the response of an individual against a particular stimulus. It might be external or internal or both. For example, some aspects of human behavior depend on the other’s behavior while some of the behaviors are not causative and meaningless (Bandura 1986). Some traits of human behavior are social and depend on one’s individuality and temperament and are immutable (Skinner 1957). Torgersen (2009) told about the theory of nature that human behavior like aggression is totally depending on a person’s genes. Depending on the developmental stages, it might be possible that children’s behavior is calm, polite and responsible rather than their aggressive parents. According to two great philosophers Descartes and Plato, without any external factors like atmospheric forces or personal experiences innate traits never changed (Myres 2013). Here it can be anticipated that both nature and nurture have an equal role in building one’s behavior.

## Conclusion

Nature and nurture are all about genes and the environment respectively. Genetic fitness and the surrounding environment both are very important

for the proper development of a person. So this is not right to give priority to one of both, nature and nurture, as both are equally responsible for one’s personality, health, intelligence, social aspects, etc.

The debating topic of nature versus nurture in determining the person’s individuality never ends with one view. It always supports the interactive approach of determination, i.e., a vice versa relationship between both nature and nurture. Also, diversification among the huge population is not limited to these two factors, the behavior and character of the individual is a multifactorial approach.

After going through several examples and theories, the debating issue between nature and nurture got more entangled. One group of science, dealing with the inherent characters of an individual, targets the nature side for the kind of actions an individual performs, while the other side of science, i.e., psychology, moves its attention toward the nurture-targeted human behavior development. The third view of some of the researchers points out the collective approach in evaluating the behavioral patterns of an individual, i.e., both the genes as well as the surrounding environment influence common acts.

Hence, we can conclude that around 50% of the behavior might be governed by the genes that we inherit from our parents as each gene has codes for a particular type of action and in total internally masks the individual’s way of presenting themselves to the society. The other half is a learned behavior that is conditioned by interacting with the environment provided to them. Therefore, both nature as well as nurture present their crucial places in influencing the individual’s behavior.

The interaction between the genes and environment is a two-way criteria that defines the pattern of the act and the character as such. The social responsibilities of an individual are also headed under the vice versa interaction of these two entities. This topic tests one’s intelligence and thoughts for giving importance to one of these two approaches and decide whether nature governs their behavior or nurture. But with the help of several studies and different theories of great

researchers from different areas of science, it can be concluded that both nature and nurture play a crucial role in maintaining one's life well. Both are related to each other. If either one will be affected, the other will automatically get affected. For example, the current situation which is the worldwide pandemic attack of Covid-19 (a deadly virus) can be spread by touch, sneezing droplets, and even nearby air of an infected person. At this time, peoples are suffering from such a huge problem of health issues, starvation, economic crisis, etc. because of a virus named Corona. This virus is infecting our community. It can attack easily the person with weak immunity, so in this condition one should try to not go out and just stay at home and take the necessary precautions; only by this one can change this environment and get rid of this problem. On the other hand, people with good immunity can become a carrier of the said virus. Possibly they can't get affected but they can affect the related community as this virus can spread with touch or even via a close environment. In this case, such a person should also avoid going out. At present, this is the only possible solution for breaking the chain of infection and saving our community as well as the environment. This is as simple as Darwin's theory which explains that adaptations according to that of the environment can raise the rate of survival. Further with the help of a said example, we can summarize that nature (one's physical condition) and the nurture (one's surrounding environment) are interrelated and play a crucial role not only in one's development but his survival also. If one gets affected, then others will definitely be getting affected and the results will be frightening.

Compiling the above studies of the topic named "nature versus nurture," it should be notified that instead of trying to find which is more important either nature or nurture, one should try to understand the importance of both the nature and the nurture with respect to human development as well as the survival of other animals. The environment can exist without the presence of humans but human beings can't survive without it. Being on top of the animal kingdom, it is the responsibility of human beings to understand the importance and follow the rules of the natural world.

## Definition

Navigation by honey bees refers to the cognitive and behavioral mechanisms bees of the genus *Apis* use to move between a location and one or multiple goals. These involve the evaluation and integration of direction and distance cues as well as the learning of specific places. For honey bees, goals can be as diverse as the colony nest, a foraging site, a new nesting site, or an open-air mating area.

## Introduction

The vast majority of the about 20,000 known bee species are central place foragers: adults collect and bring back resources (flower nectar and pollen, water, resins) in a stable nest where they raise their progeny (Michener 2007). Foraging requires navigation skills to locate resources, travel between them, and return to the nest. Many bees

must also navigate at some point in their life to find mating partners, a new suitable nesting site, or even to orient inside their dark nests.

About a century of research on insect navigation, starting with pioneering work of Turner (1908) and von Frisch (1967), shows that these navigation behaviors are sustained by a cognitive “toolkit” (Wehner 2009) involving celestial cues (typically a **sun compass**), a distance estimator (**odometer**), a system for integrating both information (**path integrator**), and the ability to learn **visual landmarks** and specific places (see Fig. 1a and Glossary). For bees, these mechanisms sustain the expression of different types of spatial behaviors that change as individuals learn and gain experience with their environment.

In this entry we describe these spatial behaviors in honey bees (Fig. 2), a group of 11 species and 44 subspecies (Lo et al. 2010) exhibiting some of the most advanced levels of social forms in the animal kingdom, characterized by a reproductive division of labor (fertile queens and drones, sterile workers), cooperative breeding, and overlapping generations of adults. Navigation skills are required by individuals of the different castes (Seeley 2010). The foragers collect food, water, and resins from plants. The scouts must find new nesting sites. The reproductives must find mating partners for reproduction. And the in-hive workers move between important places in the nest, such as brood cells, honeycombs and the nest entrance. All these tasks require the ability to explore the environment, identify and learn places of interest, and sometimes communicate spatial information to nestmates.

Here we focus in particular on the Western honey bee (*Apis mellifera*) as this species has a long history of domestication for honey production and crop pollination and is a model for the study of insect navigation. We discuss the different types of flights exhibited by foragers because they have been best described, especially since the development of automated tracking systems that record bee movements over several hundred meters (e.g., harmonic radar: Riley et al. 1996). However similar behaviors are expected by scout and reproductive bees. In-hive navigation has been less studied and is therefore not discussed.

## Exploration Flights

Western honey bees hatch in a dark nest, visually isolated from the outside environment. After about 2 weeks, they become foragers, which mean that they collect plant resources, sometimes scattered over several kilometers around the nest, to provision the colony. While foraging, the bee engages in different types of exploration flights during which it acquires visual memories of salient features of its environment, presumably in the form of **snapshot memories** (Collett et al. 2013), to guide future foraging trips.

On its first few excursions outside the colony nest, a bee engages in peculiar flight sequences known as “learning flights” (Fig. 1b), during which the bee learns the skyline **panorama** and **visual landmarks** associated with its nest location (Zeil 2012). Learning flights are composed of many convoluted maneuvers, loops, arcs, and zigzags facing the nest. During the initial learning flight, the bee slowly increases the radii of the loops and arcs, distancing itself from the colony nest until a point when it returns home without bringing back any resources. On the next few flights, the bee flies a bit further, slowly gaining experience with the outside environment.

Once a visual memory of the nest location is acquired, the bee engages in “orientation flights” (Fig. 1c), this time turning back to the nest. The bee flies along extended loops anchored at the nest location and covering a narrow angular sector in a given direction. Successive orientation flights are longer loops covering other sectors of the environment until every direction has been covered (Capaldi et al. 2000). During this process, the bee orients itself and searches for flower sites. If the bee is caught and released at an unfamiliar location outside the area covered by its previous flights, it engages in an extended search for its nest. By contrast, if the bee is released at a familiar location, it flies straight back home (Degen et al. 2016). Drones (males) have also been shown to be faster to relocate the colony nest after several exploration flights, allowing them to come back home from the drone congregation area if they failed to mate a queen.

**Navigation by Honey Bees, Fig. 1** (a) Environmental cues used by honey bees to navigate. Bees use the position of the sun in the sky (or polarized light dashed lines under cloudy conditions, dashed lines) as compass. They learn visual landmarks (e.g., trees, rivers, paths) and views of broader visual cues like panoramas and skyline (i.e., snapshots). When closer to the goal, bees use local available information to pinpoint the goal (e.g., shape, color, odors). (b, c, d) Hypothetical examples of flight sequences performed by a forager as it gains experience. (b) Learning flights: during its first excursions outside the hive the bee learns the visual scene characterizing the nest entrance

using concentric circles increasing in size (red plain lines). (c) Orientation flights: after a few trips, the bee starts exhibiting sequential exploration of sectors around the nest (orange dashed line) to find flower patches. (d) Route following and homing: once experienced, the bee follows a multi-destination route (trapline) learnt from previous foraging trips (dashed orange line). The bee returns home following a home vector computed through path integration (inbound in green). At the end of this homing flight the bee corrects eventual path integration errors through small search loops to precisely locate the nest entrance

Exploration flights are not exclusive to first trips outside the nest, but also occur during the foraging process. For instance, once a food resource is found, a forager may exhibit learning flights to learn the visual scene surrounding this

new site so that it can more easily return to this site on subsequent foraging trips (Robert et al. 2018). When a resource is depleted, the bee searches for an alternative site through longer flights centered at the familiar depleted location. These

**Navigation by Honey Bees, Fig. 2** Honey bees contain 11 species. Dwarf open nesting honey bees like *Apis florea* are the most basal group and live mostly in Asia and Middle East. The open nesting giant honey bees like *Apis dorsata* are found only in Asia. The most recently derived group are the cavity nesting honey bees represented by six species: five of which are distributed in Asia. *Apis*

*mellifera* has a natural distribution in Africa, Europe, and the Middle East, but has been domesticated and distributed throughout the world. It is now found in the wild on all continents except Antarctica. Photo credits: Dwarf and cavity bees from Naila Even, giant bees from Benjamin Oldroyd. Phylogeny modified from Lo et al. (2010)

exploration flights, composed of straight segments and turns, have Lévy characteristics, meaning that there is a larger proportion of long flight segments than one would expect from a normal distribution (i.e., a Brownian search) (Reynolds 2008). This type of random search pattern is expected to be optimal to locate patchily distributed food sources, like plants, for animals with little knowledge of their environment.

## Homing Flights

At the end of every foraging trip, a forager must navigate back to its nest to unload its crop and feed the colony. “Homing flights” are composed

of two phases: a straight line flight to return to the nest area, and a convoluted flight to pinpoint the nest entrance (Fig. 1d).

To return home, the bee uses its estimation of directions and distances of the often tortuous inbound path toward a goal (e.g., feeding site) and integrates both information using a **path integrator**. In honey bees, directions are primarily estimated through the position of sun in the sky, constituting a **sun compass**. When the sun is not directly visible (e.g., during cloudy days), this information can be retrieved from the pattern of **polarized light**. Distances are estimated using an **odometer** through the quantity of visual information perceived on the retina of the compound eye while flying. It is possible to study this mechanism

in bees by making them fly in narrow tunnels with black and white strips of different widths, thereby making them under- or overevaluate their real flight distances (Srinivasan 2011).

When the crop (stomach) of the bee is full of nectar or its tarsi are packed with pollen grains, its motivation to return home sets a new directional aim: the nest. A straight line return (also called “beeline”) is then indicated by the opposite of the integrated vector during the inbound journey. During the homing flight, the bee also integrates the distance and direction traveled, shrinking the integrated vector pointing to the nest. A central part of the bee brain, called the “central complex,” receives and integrates inputs of directions and distances from diverse internal senses like eyes, body hair, wing muscles, and other brain parts, and allows all these neural computations (Stone et al. 2017). The integration process is subject to noise accumulation during the journey of the bee. To reduce this error, foragers also refer to **visual landmarks** learned during previous flights to pinpoint directions and goals (Srinivasan 2011). Anything salient in the environment can be used as visual landmarks, even elongated structures on the ground such as rivers, edges, and paths (Menzel et al. 2019).

The last bit of the homing flight (also known as “view-based homing”) is guided by visual landscape cues. Since the seminal experiments of Bouvier (1900), showing that bees locate their nest entrance with surrounding visual cues, bees have been challenged to pinpoint their home in a plethora of scenarios. Objects may be displaced closer to or further away from their nest, displaced to a new location, replaced with smaller or differently colored one, or even camouflaged (Dittmar et al. 2010). Based on these studies, we know that bees learn relations between a myriad of visual cues and their nest entrance. These relations are not necessarily explicit. Indeed, the use of **panoramic skyline snapshots** around the nest entrance is sufficient to guide a simulated bee toward its home (Towne et al. 2017).

Two navigational routines, **path integration** and visual guidance, jointly lead a bee home (Hoinville et al. 2018), but the importance of the routines depends on the context, such as the

foraging experience of an individual bee. For instance, **path integration** tends to be preferred over **visual landmarks** in a novel environment. However when both navigational routines are conflicting, **visual landmarks** are favored (Kheradmand and Nieh 2019).

## Route Following

After several foraging trips, foragers tend to develop routes to efficiently return to known profitable feeding sites. Bees can famously be trained to learn straight line outbound paths between the nest and a feeder providing large amounts of sucrose solution (von Frisch 1967). However, in many natural conditions, bees may visit hundreds of flowers, sometimes dispersed over several kilometers, to fill their crop with nectar (honey bees have been observed homing after being released 11 km from their nest (Pahl et al. 2011)). When this is the case, foragers therefore need to develop more complex circuits between multiple goals, a routing challenge analogous to the well-known Traveling Salesman Problem (TSP) in mathematics.

A naive honey bee forager first visits flowers in an unordered sequence as it discovers them. However with experience, the bee can develop a stable route linking multiple flowers, a behavior described in many other pollinators (e.g., bumblebees, bats, hummingbirds) and known as **trapline** foraging (an analogy of the routes used by trappers to check their traps; Fig. 1d). This behavior was discovered by observing individual bees foraging in small arrays of artificial flowers within 100 m from the hive (Buatois and Lihoreau 2016). As long as the artificial flowers were regularly replenished with a sucrose reward, the bees learned to revisit them and adjusted their visitation sequence in order to minimize overall travel distances, ultimately selecting the shortest possible route (i.e., thus solving the TSP).

Computational models attempting to decipher the cognitive mechanisms underpinning this navigational feat show that trapline development and optimization can emerge based on the ability of bees to learn sequences of places using visual

memories (Collett et al. 1993) and estimate travel distances with **path integration** (Srinivasan 2011). According to these models, at the end of its foraging trip the bee may sum the straight line distances between successively visited flowers and derive the net length of the entire route. By comparing successive routes, the bee could thus increase its probability of reusing the vectors composing the shortest experienced route (Lihoreau et al. 2012). Through trial and error, this simple learning process may enable the development of good (if not optimal) routes in environments with different numbers and spatial configurations of feeding sites (Reynolds et al. 2013).

### Place Communication

Once back in the hive, the honey bee forager can communicate the direction, distance, and quality of a discovered feeding site via a sequence of movements known as the “waggle dance” (von Frisch 1967; Fig. 3). Scout bees also use this communication system to indicate the location of a suitable nesting site (e.g., cavity, hive) to reach a

consensus about the best available site before swarming (Seeley 2010).

While this ability to recruit nestmates for profitable places was discovered by naturalists long ago (e.g., Aristotle), the symbolic meaning of the dance was finally decoded by Karl von Frisch. In 1919, von Frisch trained bees to forage on feeders containing sucrose solution placed around the hive. He observed that the foragers returning to the hive performed energetic rounds and were occasionally followed by other bees who would then fly to the communicated feeder. von Frisch described two types of behaviors referring to them as “dances” depending on the distance of the food source to the hive. For feeders within 90 m the hive, foragers performed a round movement, where for longer distances they performed a wagged movement following an eight-shaped figure. It is now accepted that both dances are in fact a single behavior, whose precision varies with the distance of the food source to the hive (Griffin et al. 2012).

During the waggle dance, the forager waggles its abdomen and moves toward the direction of the food relative to the sun. In cavity nesting honey bees, like the Western honey bee, the invisible sun

**Navigation by Honey Bees, Fig. 3** The waggle dance. Upon returning to the colony nest following a successful foraging trip, a honey bee forager can communicate the location of the discovered food site to its nestmates by performing a waggle dance. The bee communicates the direction of the resource by wagging in the direction of the resource relative to its angle with the sun ( $\alpha$ ). The duration of the wagging movement is proportional to the distance of the food. The bee repeats the wagging

movement coming back from the left and then from the right drawing the figure height. The more the dance is repeated the higher the quality of the resource. Any bee following the dance can thus integrate the information and leave the hive using the instruction from the dance. The waggle dance is also performed by scout honey bees to communicate the location of a new nest site before swarming. Modified from Emmanuel Boutet (CC BY-SA 2.5)

in the dark hive is encoded by the vertical vector facing up (i.e., against gravity). Therefore, the angle between the waggle trajectory and the vertical of the comb represents the angle of the food source and the sun. In open nesting honey bees, however, the dance occurs horizontally on the top of the single frame and the dancing bee faces directly the direction of the food or the future nest. In both open nesting and cavity nesting honey bees, the distance of the food source is communicated via the duration of the waggle movement that correlates with a distance in meters. This correlation and the precision of the duration slightly varies between species and subspecies of honey bees (Beekman et al. 2015). The rewarding value of the resource is communicated by the total duration that the bee performs repeating the eight-shape dance. Dancing for a longer time increases the probability to recruit foragers susceptible to be interested by the navigation instructions for a new resource (Seeley 2010).

## Migration

Several *Apis* species from tropical Asia, such as the cavity nesting honey bee (e.g., *Apis cerana*), the giant honey bee (*Apis dorsata*), or the dwarf honey bee (*Apis florea*), do not remain in a stable nest but can abandon the nest or migrate over long distances to respond to local food shortage (Oldroyd and Wongsiri 2009, Fig. 2). Giant honey bees, for instance, have been reported to migrate to destinations up to 200 km away, stopping over in bivouac congregations to rest and forage. These bees can even sometimes return to the exact same tree after the migration period. During migration, Asian honey bees use dance communication to orient the swarm departure in the correct direction toward a new nest. In the case of long distance migrations, especially in open nesting giant honey bees, the direction is communicated but the distance is only indicated by a very long waggle signaling (Dyer and Seeley 1994). Sensory mechanisms used to migrate to a new location are similar to those used by honey bee foragers, including the **sun compass**, the **optic flow**, and the learning of visual landscape cues.

## Concluding Remarks

Honey bees show a unique diversity of spatial behaviours but share numerous sensory abilities and navigational strategies with other insects (see Glossary). Thus, they are key model species to study insect navigation. Understanding how a tiny brain, with about one million neurons, uses computations to navigate efficiently in three dimensions over large spatial scales, finds direct applications in algorithmic and robotics and may help understand how these mechanisms evolved in the more complex brains of vertebrates (Chittka and Niven 2009). Some features described in mammal navigation studies, like the hypothesis of the representation of the global surrounding in a single mental map (i.e., cognitive map), influence debates about mental representations of space in insects (Menzel 2019). Even though no consensus has been yet reached, most studies show that **path integration** and visual guidance are sufficient to explain the complex spatial behavior exhibited by honey bees and other insects (Webb 2019).

The study of the neural mechanisms underlying navigation in the insect brain may address this important knowledge gap and clarify whether honey bees use cognitive maps. Deep brain structures start to be linked to navigational functions such as the central complex for **path integration** and the mushroom bodies for visual memories (Webb and Wystrach 2016). Exploring brain function in vivo in a flying insect in its natural environment is still out of reach. However, recent advances in virtual reality setups (e.g., Buatois et al. 2018) and onboard neuron-stimulator or recorders (e.g., Sato et al. 2015) increase the possibilities to study navigation under tightly controlled, yet ecologically relevant, conditions while exploring brain function.

## Glossary

**Central place foraging** Foraging behavior consisting in collecting resources in the environment and carrying them back home. In the case of honey bees, foragers make back and forth trips between resource sites (food, water, resin) and their nest to feed the colony.

**Odometer** Mechanism enabling animals to estimate travel distances. In honey bees, distance estimation is mediated by the apparent motion of surrounding objects on the retina of the compound eye, also called “optic flow.”

**Panorama** Piece of visual information corresponding to a global visual cue, such as a landscape or a skyline. A panorama can also correspond to a combination of several visual landmarks (e.g., trees, buildings, rivers). Honey bees use panoramas for learning places such the location of their colony nest or a profitable food site.

**Path integration** Method used by an animal for knowing its current position from a reference point, also known as “dead reckoning”. Honey bees integrate odometry cues (distances) and sun compass (directions) to compute the vector pointing to a reference point (e.g., the nest) from their current position. This computation allows a honey bee to come back to the nest in a straight line.

**Polarized light patterns** Rayleigh scattering creates patterns of polarized sunlight, which are distributed in the sphere of the sky following concentric circles with the sun as a center (see Fig. 1a). With photoreceptors located in the dorsal area of their compound eyes, honey bees can detect direct sunlight as being the unpolarized area of the sky and can sense that polarization increases when the e-Vectors (electric vectors of light) are further away from the sun along the concentric circles.

**Snapshot** Learning of a 2D image at one point in time. For a honey bee, the memorized view corresponds to a specific orientation of the bee relative to the image, similar to a camera objective taking a snapshot from a specific angle.

**Sun compass** Utilization of the sun’s position in the sky as a directional guide. For honey bees, the position of the sun can be perceived directly (when the sun is visible) or indirectly through the pattern polarized light (when the sun is not visible). To orient when the sun is visible, bees can use the light intensity (higher closer to the sun) and the chromatic gradients (toward green in solar region to UV in the antisolar region).

**Trapline** Repeatable sequence of flower visits, starting and ending at the nest. With experience, honey bee foragers tend to develop traplines minimizing overall travel distances between familiar feeding sites. These routes are based on individual experience.

**Visual landmark** Salient feature in the visual scene. Honey bees can use many types of landmarks spanning from 3D trees or buildings to 2D elongated patterns on the ground (e.g., paths, edges, rivers, roads).

## Need Reduction

José E. Burgos

Centro de Estudios e Investigaciones en  
Comportamiento, University of Guadalajara,  
Guadalajara, Jalisco, Mexico

## Synonyms

**Need:** Necessity; Desire; Wish; Indispensability  
**Reduction:** Decrease; Diminution; Lowering;  
Lessening

Like most of the terms they use, psychologists have purloined “need” and “reduction” from ordinary language. According to the *English Oxford Living Dictionary* (<https://en.oxforddictionaries.com/definition/need>), the ordinary term “need” could be a verb or a noun. As a verb, it means “to require (something) because it is essential or very important rather than just desirable” and “Be necessary.” As a noun, the term means “Circumstances in which something is necessary; necessity,” “A thing that is wanted or required,” and “The state of requiring help, or of lacking basic necessities such as food.” The term “reduction” means “The action or fact of making something smaller or less in amount, degree, or size,” and “The amount by which something is made smaller, less, or lower.”

Psychologists’ uses of the expression “need reduction” have preserved these ordinary meanings. Generally, psychologists view a need as a state (a temporary condition) that results from the relatively prolonged absence or lack of something, but can be lessened by its reappearance. Widely studied examples are basic biological needs such as hunger. Psychologists have defined hunger as a need for food that results from a relatively prolonged food deprivation, and is

reduced by the return of food, or so many psychologists have assumed.

Theorizing about the role of this reduction in psychological phenomena was central to classical learning theory. Hull (e.g., 1943) was the first to propose a theory of reinforcement learning as need reduction. His observations came primarily from maze learning (typically T mazes), where animals, typically hungry rats, had to learn to navigate through a maze following a certain required path, from a start box to a finish or goal box (see “goal,” this volume) where food was available. Intuitively, Hull’s proposal was that hunger motivated or drove rats to navigate through the maze to obtain food. Obtaining the food as a result of this navigation reduced the need for food, which reinforced the stimulus-response (S-R) associations that the animal had learned from previous successful navigations, and allowed it to navigate the maze ever more efficiently and effectively.

Hull formulated his theory of reinforcement as need reduction in terms of his famous (abridged) state equation  $sE_R = sH_R \times D$ , where  $sE_R$  denotes the reaction potential (which determines the probability of occurrence of a response  $R$  to a stimulus  $S$ ),  $sH_R$  the habit or S-R associative strength (determined by conditioning), and  $D$  the drive level (determined by the level of food deprivation). As  $D$  increases (thanks to a stronger need),  $sE_R$  also increases,  $sH_R$  being equal. Getting the food at the finish box, after navigating the maze in a certain required way, reduced the need by some amount, which in turn reduced  $D$ . This reduction, in turn, increased  $sH_R$ , which maintained  $sE_R$  relatively high. When there was no food in the finish box,  $sH_R$  decreased but  $D$  increased again, also maintaining  $sE_R$  relatively high.

Reinforcement as need reduction is squarely framed within the *drive* theory of motivation (see “drive state,” this volume), according to which needs drive or *push* the animal from the inside to perform certain actions conducive to reducing the need. Another theory is *incentive* theory, according to which behavior is determined by incentives, external stimuli that create needs (e.g., as when someone says “I need that car”

upon seeing a brand new car) and *attract* the animal towards the stimuli. The causes of behavior in this theory, then, are extrinsic to the animal. The two theories are compatible.

Incentive theory has promoted theorizing about needs other than hunger, and to speak of “need satisfaction” instead of “need reduction.” As part of this further theorizing, psychologists have distinguished between lower needs and higher needs. This distinction became important because lower needs, in and of themselves, did not suffice to explain the persistence of learned behavior without primary reinforcement (i.e., without need-reduction). Higher needs were thus introduced to explain behavior that does not seem to be directly and immediately motivated by the reduction of basic biological needs.

Drive theorists too made this distinction, or something close enough. Hull (and many others) postulated the notion of “secondary reinforcement” to explain the maintenance of maze-movement behavior in the (temporary) absence of reinforcement. The food served as a “primary reinforcement” of the immediately preceding S-R association, and this association as a “secondary reinforcement” of the immediately preceding association, and so on. Hull thus viewed maze learning as the formation of a chain of S-R associations, much of which consisted of secondary reinforcement that kept the animal moving through the maze in the temporary absence of reinforcement. In effect, rats learned to need to, say, turn right upon seeing the right corner of the maze. This learned need was reduced by performing this response, which served as a secondary reinforcement of other, antecedent learned needs.

Hull explicitly framed his theory of reinforcement as need reduction within an adaptive, Darwinian account of behavior. Hull also formulated his theory in terms of “neural mediating structures” and “mechanisms,” which inspired the study of the neural substrates of reinforcement in more empirical detail. Unfortunately, the neuroscience of learning was very incipient in Hull’s time, which did not allow a study of specific neural mechanisms of learning.

These mechanisms are now known in much more detail, and, ironically, have unraveled a far

more complicated story than classical learning theorists ever imagined. Just a little over a decade after Hull’s 1943 book, Olds and Milner (1954) reinforced rats for pressing a bar by just electrically stimulating the septal area (stimulating other brain structures did not have a positive reinforcement effect), *without any deprivation of food or water*. The acquisition curves were comparable to those obtained with food as reinforcer. Clearly, there is no need or drive here, just electrical stimulation of certain brain areas, and yet, there was significant learning.

Moreover, given a *choice*, hungry rats prefer direct brain electrical self-stimulation over food, to the point of starvation, a phenomenon known as “self-deprivation” (for a review, see Frank and Stutz 1984). Need reduction, then, is not necessary for learning. These early studies led to many others that have yielded identification of *dopaminergic* structures (e.g., ventral-tegmental area, nucleus accumbens, medial forebrain bundle, etc.) as key to associative learning, operant as well as Pavlovian. These structures have also been shown to underlie the effects of addictive drugs such as cocaine (for a review, see Wise 2006).

Choice complicates the matter, leading to another field where talk of need satisfaction has gone well beyond basic biological needs. This field is known as “economic psychology” or “behavioral economics,” the interdisciplinary relations between economics and psychology. At the heart of this field is the study of the determinants (external, internal, social, cultural, biological, etc.) of economic choices or decisions, where agents must decide which action to perform, among a set of alternative actions, based on cost-benefit judgments. To be sure, a rat in a T maze must decide whether to go left or right, but in the classical studies there was no choice between different kinds of foods (e.g., sweetened vs. salty). When animals, human and nonhuman alike, are faced with this kind of decision situations, needs and their satisfaction become exceedingly complex affairs where incentives play a more central role.

One insight this field has led to is that, in such kinds of situations, humans do not seek to satisfy needs like the ideal, perfectly rational agent, the *Homo economicus*, economists have postulated.

The research of Daniel Kahneman and colleagues, which earned him the Nobel Prize in 2002, was instrumental in this regard. Their results suggest that humans, when seeking to satisfy economic needs, repeatedly fall prey to a number of logical fallacies. For example, the conjunction fallacy (e.g., Tversky and Kahneman 1983) is to infer that a conjunction (e.g., “I will get paid today and tomorrow”) is more *probable* than either of its conjuncts individually (e.g., “I will be paid today” *or* “It will be paid tomorrow”). What makes it a fallacy is the multiplication rule of probability, according to which the joint probability  $p(A \& B)$  for independent events  $A$  and  $B$  (where “&” or “and” take their strict logical sense) equals  $p(A) \times p(B)$ . Since probabilities are numbers between 0.0 and 1.0,  $p(A) > p(A \& B) < p(B)$ . Another fallacy is the gambler’s fallacy, the belief that occasional highly frequent occurrences are more probably followed by lower frequent occurrences. Committing these and other fallacies, Kahneman and colleagues argued, leads to unsound economic decisions to satisfy economic needs. However, as Gigerenzer et al. (2008) have pointed out, Kahneman’s conclusion arises from too strict an interpretation of the term “probability” (and “and,” in the case of the conjunction fallacy) that does not always obtain in ordinary language and common sense.

Another important phenomenon is delay discounting (for a review, see Odum 2011). In this phenomenon, the reinforcing value of a reward decreases hyperbolically with its delay relative to a required response. This function predicts behaviors like impulsivity, the preference for a smaller but immediate over a larger but delayed reward. This kind of behavior is yet another challenge to the classical learning theorists’ rather simplistic view of the role of reward magnitude in need reduction. Contrary to such view, animals do not necessarily seek greater rewards.

There has also been much research on the neuroscience of economic decisions, or neuroeconomics (for a recent review, see Glimcher and Fehr 2013). This research has shown that some of the same neural substrates of simple animal learning also underlie complex economic decision-making under risk (where some

decisions could lead to significant losses) and uncertainty (where relevant information is unavailable). For example, increases in the activity of parts of the prefrontal cortex such as the frontomedian cortex (e.g., Volz et al. 2003) and frontoparietal cortex (e.g., Paulus et al. 2001) have been linked to decision-making under uncertainty. Increases in the activity of the insular cortex have been linked to decision-making under risk (e.g., Paulus et al. 2003).

Talk of “needs” remains widespread in neuroeconomics and behavioral economics research, although, again, with a much wider meaning beyond basic biological needs like hunger, to include many other kinds of needs (e.g., the need to say, do, buy, know, ignore, change, learn, or decide things that do not directly or immediately involve getting food). Talk of “need reduction” has declined significantly, giving way to talk of “need satisfaction” and becoming more historically than theoretically or empirically relevant.

## Need: Necessity

### ► Need Reduction

## Negative Reinforcement

Emma L. Horton  
Oxford Brookes University, Oxford, UK

### Definition

Negative reinforcement is a concept within operant conditioning which involves the strengthening of a behavior via the removal of negative stimuli as a consequence of the behavior. Such negative reinforcement increases the probability of the behavior being repeated.

For example, the behavior of visiting a dentist is negatively reinforced by the removal of toothache. Such negative reinforcement increases the probability that an individual will repeat the behavior and go to the dentist again in the future.

## Introduction

It is natural to adjust behavior in response to good and bad consequences. Throughout life individual behavior is constantly shaped by reinforcement and punishment. Experiments by the American psychologist Edward Lee Thorndike (1911) were among the first to highlight how the consequence of a given behavior can affect the likelihood of it being repeated in the future. The concept being that in a given situation, without thought process, an organism will exhibit a range of behaviors, and a behavior followed by a desired outcome is more likely to be a behavior that the organism will repeat. He coined this the “Law of Effect.” Thorndike uses the example of a cat escaping a box via unlatching a door and noted that each time the cat was placed in the box, the behavior which led to unlatching the door occurred earlier.

Later American psychologist, Burrhus Frederic Skinner, likewise conducted research on how consequences of behavior affect the probability of individuals repeating such behavior. In 1937 B. F. Skinner coined the term “Operant Conditioning” – meaning changes in the probability of responses as a result of changes in the consequences of such responses. In one of his books, B. F. Skinner described the following example: a pigeon is fed via a food tray immediately after raising its head above a predetermined point; this leads to the frequency that the pigeon’s head is above the point increasingly, very quickly the bird’s posture has changed, and its head very rarely falls below the predetermined point. Within operant conditioning the unit of behavior is known as “the operant” which in this case would be “the pigeon raising its head.” Initially this response is a spontaneous behavior but reinforced (strengthened) via being rewarded with food (the reinforcer) and thus increases in frequency.

Reinforcing events were described by B. F. Skinner as those which increase the probability of a given response occurring again, and he described two types of reinforcing events: those which involve adding a positive stimuli (positive reinforcement) and those which involve removing negative stimuli (negative reinforcement). He also described two other forms of operant conditioning: those which involve adding negative stimuli (positive punishment) and those which involve removing positive stimuli (negative punishment).

## Negative Reinforcement

One particular form of behavioral learning is via negative reinforcement. Negative reinforcement consists of the removal of negative stimuli as a consequence of a behavior. Both escape and avoidance behaviors remove negative stimuli. Behaviors which involve the organism getting away from an existing negative stimuli are known as escape behaviors. Whereas behaviors which prevent the onset of negative stimuli are known as avoidance behaviors. For example, a child may touch a hot cooker and feel burning and therefore remove their hand from the surface. The behavior of removing the hand was cued by the feeling of burning, which was negatively reinforced by the burning feeling stopping. This is an escape behavior. However, over time the child learns not to touch the cooker, a negatively reinforced avoidance behavior.

## Antecedent Cue

The negative reinforcement of a behavior will increase the frequency at which it occurs in the future. However, behaviors do not have the same effects in all situations, and therefore situational cues are important. Cues which precede behaviors are known as antecedent cues and are used by organisms to decide if a given behavior is likely to have a positive or negative consequence. Thus, antecedent cues come before a given behavior, and consequences proceed it. When a behavior is

reinforced, it is more likely to be repeated in the future in response to the correct antecedent cue, that being a stimulus that cues an organism to perform a reinforced behavior in order to receive an associated reinforcer. For example, the onset of illness is an antecedent cue for going to the doctors in order to receive medication, which removes the symptoms of illness. From a young age, we are negatively reinforced to seek help from a parent, pharmacist, or medical professional in order to remove symptoms of illness, and therefore symptoms of illness become the antecedent cue for the behavior of seeking help. The consequences of a given behavior both influence the likelihood that behavior will happen again and the ability of an antecedent cue to result in a given behavior in the future.

## Contingent Consequences

Operant conditioning is the most effective when consequences immediately follow the behavior or are directly related to the behavior and the association between the behavior and consequence can be detected by the individual, i.e., the consequences are contingent. For example, the immediate removal of intense pain after moving your hand off a hot surface negatively reinforces this behavior as there is an immediate and direct link between the behavior and the consequence. However, while the behavior of quitting smoking is negatively reinforced by improving health, an individual may not see immediate removal of related health issues such as coughs and shortness of breath. Despite this the long-term health improvements are negatively reinforcing as they are a contingent consequence detectable by the individual. Generally, consequences not related to the behavior but immediately following will not affect the frequency of the behavior as the individual may be aware the two are not associated, i.e., winning the lottery directly after quitting smoking is not going to positively reinforce the behavior of not smoking, as the individual can detect the two are not related.

## Negative Reinforcement and Punishment

Punishment works in the opposite direction to reinforcement. It involves a negative consequence following a behavior, reducing the frequency at which the behavior occurs over time. Many behaviors are learned via a combination of both reinforcement and punishment. For example, the behavior of driving at a speed above the limit is positively punished by the addition of a fine or negatively punished via the removal of a driving license. This addition of negative stimuli, or removal of positive stimuli, as a result of the behavior of driving above the speed limit reduces the probability the individual will repeat the behavior in the future. Equally, the behavior of driving below the speed limit is negatively reinforced by the consequence of not receiving a fine, and thus the individual is more likely to repeat the behavior of adhering to the speed limit in the future. Punishment often occurs alongside negative reinforcement. Negative consequences can both punish behaviors and cause a reduction in their frequency and result in escape and avoidance behaviors to be learned via negative reinforcement.

## Extinction and Punishment

The frequency a given behavior occurs at, as a result of positive or negative reinforcement, can reduce over time, as a result of processes such as extinction and punishment. Reinforcement increases the frequency at which a given behavior occurs and maintains that behavioral frequency. If such reinforcement is stopped, the frequency of the behavior is likely to decrease over time, and this process is known as extinction. Likewise, if an alternative behavior now results in greater reinforcement, the individual may switch to that behavior. Operant behaviors learned via negative reinforcement to avoid or escape negative stimuli can reduce in frequency should such negative stimuli no longer be present. However, avoidance behaviors learned as a result of negative reinforcement can persist long after elimination of the

negative stimuli. This is due to individuals avoiding behaviors linked to negative stimuli and therefore not learning that the negative stimuli are no longer present. Punishment usually works faster than extinction in reducing the frequency of a behavior, especially if the punishment is strong and not counteracted by reinforcement. Likewise, punished behaviors can recover (increase in frequency) once punishment ceases, and the rate at which this occurs is linked to the severity of punishment, with milder punishment linked to quicker recovery. If both punishment and reinforcement are acting on a behavior, the cost-benefit ratio, and frequency of each, affects the outcome on the behavior. An alternate behavior may be switched to if it offers a more favorable cost-benefit ratio.

## Conclusion

Negative reinforcement is an effective way to alter the frequency an individual exhibits a behavior and is naturally encountered and forms part of behavioral learning in individuals throughout their lifetime. In addition it is now actively used by scientists and captive animal professionals as a behavioral training technique to study and shape animal behaviors. Antecedent cues are important in stimulating such learned behaviors, contingent consequences essential in consequences being reinforcing, and reinforced behaviors do not persist indefinitely if reinforcement is not sustained, or behaviors are acted on by opposing forces such as punishment or more reinforcing alternatives.

## Neocortex

James C. Dooley  
Department of Psychological and Brain Sciences,  
University of Iowa, Iowa City, IA, USA

## Synonyms

[Isocortex](#); [Neopallium](#)

## Definition

The neocortex is a portion of the cerebral cortex found exclusively in mammals. It is a six-layered structure, broken into distinct areas, each with their own laminar appearance, connectivity, and functional properties. Its organization, accessibility, and

size (particularly in primates) have made it one of the most studied portions of the brain.

## Laminar Structure

Perhaps due to its prominence in humans, the neocortex has been the subject of extensive research for well over 100 years. As part of the cerebral cortices, the neocortex is a bilateral structure, distinct from the basal ganglia, amygdala, olfactory bulb, and hippocampus because of its extensive connectivity with the thalamus, as well as its six-layered structure. From superficial to the deep, these layers include:

- I. Molecular layer
- II. External granule cell layer
- III. External pyramidal cell layer
- IV. Internal granular cell layer
- V. Internal pyramidal cell layer
- VI. Multiform layer

These layers vary in their thickness in different parts of the neocortex, but increasingly there is evidence that all layers can be identified across the entire cortical sheet. Further, while the specific connections differ across the neocortex, these cortical layers form an essential part of a general thalamocortical circuit, with layer IV receiving thalamic input, layers II/III involved in cortical processing, and layer VI projecting back to the thalamus. Layer V projects to subcortical structures other than thalamus and more broadly allows for subthalamic cortical output.

## Areal Structure

Grossly, the neocortex is divided into the frontal, parietal, occipital, and temporal lobes, after the names of the bones of the skull covering these portions of the brain. These lobes are often associated with different functions, with the frontal lobe being involved in motor planning and execution, the parietal lobe processing somatosensory inputs, and the occipital and temporal lobes processing visual and auditory inputs, respectively.

Within each lobe, the neocortex is further divided into different cortical areas, with its own distinct laminar appearance, cortical and subcortical connectivity, and functional characteristics. The neocortex's modular structure has long been appreciated; however, the importance of differences in the laminar structure of different cortical areas as a marker for functionally different cortical areas gained prominence in 1909, when German anatomist Korbinian Brodmann published the location of 52 different areas in humans, based on observed laminar structure using the Nissl method of staining cell bodies (Garey 2006). Today, the exact number of cortical areas can vary greatly, depending on the species being investigated, and sometimes, the scientist being asked. However, the smallest mammals, with the simplest brains, are generally agreed to have at least 15 distinct cortical areas, while humans are thought to have over 200 (Kaas 2017).

## Sensory Areas

Each sensory modality represented in the neocortex has a primary sensory area, along with numerous secondary, or association areas. Primary sensory areas (including primary visual, auditory, and somatosensory cortex) form the most distinct laminar boundaries with the surrounding cortex, due to the density of thalamic inputs to layer IV. Generally, these primary sensory areas represent the sensory environment of the contralateral side of the body, with highly organized topographic representations of sensory space.

Primary somatosensory cortex (in the parietal lobe) represents the contralateral body surface, with the head and face represented laterally, and the legs and (when applicable) tail represented medially. This topographic representation of the body is referred to as a somatotopic representation. Importantly, adjacent parts of the body are represented next to each other in cortex. Ecologically important portions of the body often show cortical magnification, with a greater portion of the somatotopic representation taken up by these body parts compared to other, less ecologically important body parts. In humans, the hands, as

well as oral structures, show cortical magnification, reflective of the ecological importance of tool use and language production. Rodents, including rats and mice, show cortical magnification of the whiskers, as these species primarily use their whiskers to interact with the environment.

Primary visual cortex (in the occipital lobe) represents the contralateral visual field, displaying a form of topography referred to as retinotopy. Just like the adjacent parts of the skin being represented next to each other in primary somatosensory cortex, adjacent parts of the retina are represented next to each other in primary visual cortex. Further, ecologically relevant parts of the retina show cortical magnification in primary visual cortex, with primates and humans showing extensive cortical magnification of the central part of the visual field, called the fovea. In contrast, prey animals (such as antelope) often show cortical magnification of the entire horizon (called a visual streak), rather than a single point, reflecting the need to use vision to detect predators across the whole visual field.

Primary auditory cortex (in the temporal lobe) represents the auditory sensory environment by frequency, thus primary auditory cortex is said to contain a tonotopic representation. Frequency ranges represented vary by species and, like the somatosensory and visual systems, display cortical magnification of important frequency ranges.

Secondary sensory areas (also called association areas) are often conceptualized as part of a hierarchy of sensory processing. Unlike primary sensory areas, topographic representations in these areas are often more abstract and are not always complete. Additionally, association areas often show various degrees of multimodal sensory processing, with neurons in these areas maximally responding to simultaneous presentations across multiple modalities.

## Motor Areas

Primary motor cortex (in the frontal lobe) is located immediately rostral to primary

somatosensory cortex. Originally identified by intercortical microstimulation experiments at the end of the nineteenth century, it is the region of cortex where electrical stimulation, using a relatively small amount of electrical current, results in movements of muscles on the contralateral side of the body. Broadly, it is organized using a similar form of somatotopy as somatosensory cortex; however, unlike primary somatosensory cortex, this somatotopy is not present on a fine scale. Motor cortex is also called agranular cortex, because it was long thought to lack the inner granular layer (layer IV, the thalamic recipient layer). More recent work suggests that primary motor cortex, like the rest of the neocortex, does have all six cortical layers (Yamawaki et al. 2014); however, layer IV is more difficult to identify with classical methods, such as a Nissl stain.

Layer V of motor cortex contains Betz cells, the largest neurons in the neocortex. The axons of these neurons project down to the spinal cord, synapsing directly onto anterior horn cells, and forming the corticospinal tract. These neurons are thought to be responsible for the direct motor output of primary motor cortex, and are the neurons that, when activated electrically via intracortical microstimulation, cause movement. Betz cells are involved in producing dexterous movements, particularly in the arm and digits, and damage to the corticospinal tract produces a permanent deficit in these types of movements. However, lesions to motor cortex, particularly in nonprimates, do not result in paralysis but instead produce motor learning deficits, with previously learned movement patterns remaining intact. This hints at a second, but arguably equally important role of motor cortex, in directing motor learning of subcortical motor centers (Peters et al. 2017).

Anterior to motor cortex exists a large region of cortex termed prefrontal cortex. This region of the brain greatly expanded in primates, especially humans. Involved in motor planning and executive control, the exact function of many prefrontal areas has been difficult to determine. Having expanded so rapidly in human evolution, homologies with other, particularly nonprimate species, are difficult.

## Neophobia

Claudia Mettke-Hofmann  
School of Natural Sciences and Psychology,  
Liverpool John Moores University,  
Liverpool, UK

## Definition

Neophobia is the fear of the novel (neo = new, phobia = fear).

## Introduction

Neophobia elicits avoidance of novelty and protects an organism from danger. An organism

categorizes something as novel when it deviates from an innate template or what it has experienced before (Greenberg and Mettke-Hofmann 2001). Novelty can include unfamiliar space, situations, organisms (conspecific and heterospecific such as novel predators and prey), food, fluids, items, etc. Neophobia varies with the degree of novelty and organisms show more avoidance reaction the more the currently experienced deviates from what they know (Greenberg and Mettke-Hofmann 2001). However, repeated exposure to the same stimulus without negative consequences results in habituation or attenuation of neophobia (Ramos 2015) and either disregard of the formerly novel stimulus or finally approach and investigation (neophilia – attraction to novelty) to learn about the stimulus.

Several brain areas are involved in neophobia reactions though this is an active area of research; one of the main areas involved is the amygdala which is responsible for emotional reactions such as fear, whereas the perirhinal cortex and ventro medial prefrontal cortex (in mammals) are important in detecting novelty (Ramos 2015; Burns et al. 1996). The hippocampus, particularly the ventral subiculum, is another area involved in neophobia and often linked to spatial neophobia. The amygdala, hippocampus, and prefrontal cortex all communicate novelty to the nucleus accumbens (Burns et al. 1996).

Neophobia often has a genetic component and species differ in their avoidance reactions which have evolved over evolutionary times in interaction with their environment. However, experience also affects neophobia and the avoidance response expressed results from an interaction of genes and environment in most cases.

### Types of Neophobia and Brain Areas Involved in Neophobia

The distinction between novel versus familiar is a fundamental process in categorizing the environment and items therein. However, the context in which novelty is encountered seems to matter. For example, rooks (*Corvus frugilegus*) show year-round consistently high neophobia toward novel objects presented near familiar food. In contrast,

neophobia toward unfamiliar humans (which may be perceived as a predator) standing beside familiar food decreased during the breeding season maybe due to higher energy demands during this period resulting in higher risk-taking. This indicates that different mechanisms are underlying these two types of neophobia (Greggor et al. 2016). The notion that context is important is supported by brain studies as lesions to specific brain areas affect some types of neophobia but not others (Walker and Winn 2007; Burns et al. 1996). Moreover, different brain areas seem to be involved in the initial avoidance reaction and the process of attenuation during repeated presentation (e.g., Ramos 2015).

Overall, how organisms categorize novelty is an active area of research. From an evolutionary point of view, different selection pressures may act on different types of novelty. Miscategorizing food or predators can have catastrophic effects, whereas unfamiliar habitats or objects may have less drastic consequences.

**Food neophobia** is possibly one of the most researched types of novelty reactions and important in identifying how new resources are incorporated into a species' diet. It also links to eating disorders in humans – a highly researched area at the moment. When encountering unfamiliar food, animals initially try small quantities and wait for any negative digestive consequences. When there are none, they start incorporating more of the novel food. In experimental testing, familiar and novel food are presented simultaneously and the time to approach each and the amount eaten is compared. Food neophobia is closely linked to dietary conservatism – the refusal to incorporate palatable food into its own diet even after thorough investigation. While neophobia describes the initial avoidance of unfamiliar food due to its novelty, dietary conservatism refers to the time it takes to fully incorporate the food into the diet which can take months in some cases (Marples et al. 2007). Likewise, **taste neophobia** extends to the avoidance of fluids and is investigated the same way as food neophobia.

**Object neophobia** is another well-researched area and can be linked to how animals respond to changes in their environment. In an increasingly faster changing world due to global warming and

human activities, the ability of an organism to respond to environmental change is critical for population development and provides important information for conservationists how a species may fare in the future (Mettke-Hofmann 2017). To test object neophobia, a novel object is often presented besides familiar food and the animal is in conflict between the motivation to feed and the motivation to avoid the novel object. The time to start eating with and without the novel object is measured with the difference between the two representing the strength of the neophobia reaction (Mettke-Hofmann et al. 2002). Alternatively, food is substituted with a resource regularly visited such as nest boxes, water holes, etc. Repeated presentation leads to attenuation of neophobia and latencies to approach with objects converge with latencies without objects. Consequently, the novel object is either ignored or individuals start exploring the novel object.

**Spatial neophobia** represents the avoidance of unfamiliar areas and can be linked to the willingness of an animal to venture into unfamiliar habitats, range expansion, and invasion. However, it should be mentioned that the decision to enter and explore an unfamiliar environment is driven by spatial neophilia: the attraction to novelty that leads to approach and exploration of an unfamiliar environment (Mettke-Hofmann et al. 2009). Experimentally, spatial neophobia is often measured as the proportion of time spent in open (dangerous) versus closed (safe) arms of a T-maze or in the center of an open arena in rodents (Walker and Winn 2007). In birds, spatial neophobia has also been measured as the frequency of approach attempts to the novel environment from a familiar cage representing the conflict between the motivation to enter and explore the novel environment and the motivation to avoid the novel environment (Mettke-Hofmann et al. 2009).

**Neophobic predator avoidance** is a relatively new research area and specifically investigates how organisms respond to new predators. Misidentifying an unfamiliar species can result in death when encountering a predator and neophobia toward unfamiliar species can reduce this risk (Brown et al. 2016). Neophobic predator

avoidance is investigated by presenting the study species with unfamiliar species which can be other predators or nonpredatory species (control) or extracts of such species, e.g., odor or vocalization and measuring the duration of freezing, reduced activity, or time to resume feeding before and after the presentation of the stimulus.

## Ecology Shapes Neophobia

As outlined above, neophobia often has a genetic component meaning that selection can act on neophobia. While neophobia protects an organism from danger, it also prevents access to possibly useful resources such as food or other habitats. Extreme neophobia while safe would not be advantageous for an organism and selection may act on balancing costs and benefits of neophobia resulting in different degrees of neophobia between species.

Different hypotheses have been brought forward to explain neophobia reactions. The neophobia threshold hypothesis (NTH) states that experiences made during early life are later protected by neophobia (Greenberg 2003). Few early experiences result in increased neophobia later in life, whereas ample early experiences would lead to lower neophobia reactions as many situations are already known. The NTH has been confirmed in wild-caught generalist and specialist species; habitat and diet generalist species showed lower object neophobia by feeding earlier from familiar food presented in novel objects or microhabitats than closely related habitat and diet specialists (Greenberg 2003). The generalists had gained more experience with a variety of situations during young age than the specialists. Strong food neophobia has also been shown in snail kites (*Rostrhamus sociabilis*) which are extreme dietary specialists (Beissinger et al. 1994).

Another hypothesis linked to neophobia is the dangerous niche hypothesis (DNH) which predicts that animals exposed to dangerous environments are more cautious, i.e., neophobic, than animals living in a safer environment (Greenberg 2003). Support for this hypothesis comes again from comparing specialists and

generalists. In this case, hand-raised diet and habitat generalists showed more object neophobia than specialists, possibly as a consequence of the former expecting to encounter dangerous situations more often (Greenberg 2003). As hand-raised individuals were used in Greenberg (2003), intrinsic neophobia was measured as opposed to functional neophobia as in the example provided for the NTH.

Movement patterns – being year-round resident or conducting seasonal migrations – also affects object neophobia with residents being less neophobic toward novel objects placed around familiar feeding locations compared to migrants. Residents are possibly more familiar with local risks and can categorize the risk around novel objects faster than migrants that only spend a few months on the winter ground (Mettke-Hofmann et al. 2013). In contrast, migrants have been found to show less spatial neophobia than residents in concordance with the migrant-neophobia hypothesis which predicts a higher willingness and lower hesitation of migrants to enter unfamiliar environments. This helps during migration when encountering many unfamiliar habitats (Mettke-Hofmann et al. 2009).

Neophobia has also been shown to differ along an urbanization gradient but with conflicting results; in some studies, urban birds displayed less object neophobia than suburban birds, whereas in other studies, urban birds showed more object neophobia even though experimental setups were similar with placing novel objects besides familiar feeders.

Finally, food neophobia has been linked to invasion history in house sparrows (*Passer domesticus*) with actively invading populations showing lower neophobia toward novel food than established populations (Martin and Fitzgerald 2005).

## Experience Changes Neophobic Reactions

While neophobia often has a genetic component, animals develop in a given environment which results in gene–environment interactions and

the behavioral output is a mixture of both. Evolutionary this makes sense as some species may generally live in more dangerous environments, hence having a genetic predisposition to be more neophobic. However, at the same time, danger may vary between locations or change between generations. The ability to adapt neophobic reactions to such variation on the individual level is advantageous. A variety of studies on fish and amphibians have demonstrated that variation in predation risk (either naturally or experimentally induced) affects neophobic responses in different populations of the same species. Individuals from high predation backgrounds often express a heightened predator avoidance response toward any novel odor (whether from a predator or nonpredator) and also show spatial neophobia, i.e., take longer to enter an unfamiliar environment. In contrast, individuals from low predation backgrounds often do not avoid novel odors at all and enter novel environments quickly (e.g., Brown et al. 2013). For individuals living under high-predation regimes, neophobic predator avoidance reduces encounter rates and improves survival. Such predator avoidance can be rapidly induced experimentally but also fades when predation risk decreases providing a flexible mechanism to respond to local predation (Chivers et al. 2016). Brown et al. (2013) expanded the dangerous niche hypothesis (see above) to this phenotypic plasticity in neophobic predator avoidance that allows context-specific expression of neophobia toward predators. Under high predation risk, neophobia provides maximum protection, whereas under low risk, exploitation of new resources is not compromised.

However, predators also express neophobic responses when encountering unfamiliar prey (food neophobia). Mutations are often avoided by predators even when they stick out due to their oddity, i.e., novelty. This gives mutations an advantage and increases their abundance which eventually reduces their novelty effect. Over time, predators learn that this unusual prey is not dangerous and predation on them increases. It is assumed that the evolution of aposematic prey is based on initial neophobia reactions which are then maintained by toxicity

(Thomas et al. 2003). Interestingly, studies in several bird species ranging from chickens (*Gallus domesticus*) to hand-reared songbirds have shown that positive experience with novel prey (different color) can dramatically reduce neophobic reactions toward novel food even when the novel food also differs in shape and size indicating generalization (Adamova-Jezova et al. 2016). However, it is unclear whether such generalization would also happen in wild individuals which may have encountered already noxious prey.

Developmental conditions also affect neophobia reactions. Birds raised in barren environments show greater object neophobia when combined with familiar food than birds raised in enriched environments (Greenberg and Mettke-Hofmann 2001) and pigs (*Sus scrofa domesticus*) from barren environments show stronger food neophobia (Oostindjer et al. 2011). Neophobia also follows a developmental curve in many species including humans with high neophobia early in life, lower neophobia as adults, and again increasing neophobia at the end of the lifetime (Ray and Hansen 2005). The initial high neophobia may be due to their vulnerability but also inexperience resulting in most situations being novel. As an organism grows, it accumulates knowledge and it may also be in its best body condition favoring the reduction of neophobia. While knowledge further accumulates as an organism ages, body condition may deteriorate leading to higher neophobia again. Such age effects are known for object, food, and spatial neophobia in a range of species (e.g., Ray and Hansen 2005).

The social environment possibly not surprising affects neophobia responses. Animals are often less neophobic in the presence of conspecifics and are more likely to test novel food (Oostindjer et al. 2011). This may be due to social facilitation (even though other group members may eat familiar food), protection from other dangers due to the group which allows focusing on the novel food or competition to get access to a possibly new resource first. The latter is supported by findings that subordinate individuals often show less food and object neophobia which allows

them exploiting new resources before they are displaced by dominant individuals (An et al. 2011). Moreover, group size itself affects neophobic reactions with lower object neophobia in larger groups (Mettke-Hofmann et al. 2013).

## Neophobia as Part of Personality

In recent years, research has accumulated ample evidence that individuals differ consistently and predictably in their reaction to environmental challenges; this is often referred to as animal personality. This means that animals are consistent over time, i.e., when tested at time point A and respond in a particular way, they will do so again when retested at time point B. Furthermore, behaviors are often correlated with each other and form behavioral syndromes. Neophobia is often part of personality and linked to the neuroticism dimension in the human big-five personality scale. This means that individuals across the animal kingdom express different degrees of neophobia and do so consistently. It is important to mention that such behavioral polymorphism (e.g., more or less neophobic individuals) requires equal fitness to persist over evolutionary times. Different behavioral types can persist in a population due to occupying microniches, the existence of temporal environmental variation favoring different types or morphological/physiological differences between individuals. Most of the neophobia tests used in conjunction with personality have tested for object neophobia. An exception is the study by Bokony et al. (2012) who showed that object and food neophobia were correlated on the individual level, whereas predator response measured as the time to feed when a predator model is shown was not correlated with the former. Therefore, object and food neophobia formed a behavioral syndrome with those individuals approaching the novel objects quickly, also sampling the novel food quickly. These behavioral differences were consistent over time. Spatial neophobia has been shown to be consistent over time in laboratory rats though juveniles, and mature adults were more neophobic to enter a novel and open area than young adults (relative

consistency; Ray and Hansen 2005). Neophobia is often investigated together with neophilia and exploration. Neophilia is the motivation to approach and investigate novelty and exploration is usually the behavior that results from this motivation. Neophobia and neophilia are two independent motivations (Mettke-Hofmann et al. 2002) and can occur in four combinations in an organism: (a) high neophobia coupled with low neophilia resulting in not approaching novelty due to high fear; (b) low neophobia coupled with high neophilia resulting in fast approach of novelty and little neophobia; (c) high neophobia coupled with high neophilia resulting in ambivalent approach and avoidance behavior; and (d) low neophobia coupled with low neophilia resulting in no approach due to lack of interest in the novelty despite low neophobia (two-factor model; Greenberg and Mettke-Hofmann 2001). With respect to personality, some studies find positive correlations between object neophobia and object exploration (approaching a novel object at a neutral location in the cage), i.e., individuals that start foraging beside a novel object fast also approach and investigate a novel object quickly (Miranda et al. 2013), whereas other studies find a negative relationship with individuals that hesitate long to feed besides a novel object approach a novel object at a neutral location fast. This latter case can be interpreted as generally responding to novelty strongly but depending on the situation with different reactions (Mettke-Hofmann et al. 2005). Finally, some studies do not find a relationship between neophobia and neophilia. Neophobia has also been linked to reproductive success with breeding pairs responding neophobic to objects attached to their nest box having fewer successful nests and lower survival of females. Such pairs also showed less mobbing behavior toward predators (Vrublevaska et al. 2014).

## Neophobia and Cognition

Neophobia can be seen as one of the first steps in the sequence of cognitive processes after a stimulus has been perceived. Due to its function of protecting individuals from danger and keeping

organisms away from novelty, it can have far reaching consequences how animals interact, learn, and incorporate novelty into their repertoire. Eventually, neophobia can affect an organism's ability to adapt to environmental change. The consideration of neophobia in learning processes is relatively new but has been shown to considerably affect learning. For example, object neophobia often delays problem-solving as a neophobic animal interacts less with a novel item (Sol et al. 2011). While this is interesting in its own right, neophobia may overshadow differences in problem-solving ability further down the line such as the ability to combine behaviors in a new way. To exclude neophobia as a factor affecting problem-solving abilities, the focal animal first has to be made familiar with the test apparatus before setting up the problem-solving task. For instance, when an animal is tested on its ability to find a way to get access to hidden food, then it should be habituated to the apparatus which will later hide the food. This way neophobia can be excluded and, e.g., learning speed be compared between groups of animals. However, neophobia is not always correlated with problem-solving ability as some studies find higher problem-solving abilities in highly neophobic animals (Audet et al. 2015). Moreover, contrasting results have been found regarding a relationship between neophobia and different types of learning. While neophobia and associative learning (i.e., the initial acquisition of a task) are often unrelated, there is increasing evidence that reversal learning is negatively related to object neophobia with more neophobic individuals reversing learning faster (Guido et al. 2017).

A mechanism to overcome neophobia is social learning by which an animal observes others in unfamiliar situations. This is a powerful and save way to accumulate information about a novel possibly dangerous situation. However, from whom is learned and the type of neophobia concerned matters. Social learning about unfamiliar food is widespread in the animal kingdom and particularly important for young inexperienced individuals. Many organisms learn from their mother which food is safe. In social species such as pigs, food neophobia in young individuals is

reduced by observing other familiar group members but not unfamiliar ones (Figueroa et al. 2013). However, adult individuals also use social learning to assess unfamiliar situations but with interesting differences. Wild jackdaws (*Corvus monedula*) were more likely to use social information to overcome food neophobia and did so throughout the year, whereas they used social information to overcome object neophobia only during the breeding season (Greggor et al. 2016).

There is ample evidence of generalization processes with neophobia reactions. Positive experience with novel food is often generalized toward other novel food regarding a similar stimulus. Individuals of a range of species that have learnt about the palatability of a food of a particular color often readily accept similar food of a different color indicating generalization with the result of no or very low neophobia (Adamova-Jezova et al. 2016). The same is true for odors. For some species, this can even be extended to novel food that not only differs in the specific stimulus but additionally may have a different shape. Negative experience with novel food also leads to generalization but with an increase in neophobia toward novel food. Generalization of neophobic predator responses has been observed to occur across modalities. Fish from high predation backgrounds experienced with a chemical or visual predator cue generalized their neophobic response to any new stimulus whether chemical or visual (Brown et al. 2016). Generally, irrespective whether food or predator neophobia is involved, generalization is more likely to occur the more similar a novel item is to what has been experienced before. Tadpoles familiar with a predator cue (odor) of a particular predator generalized their neophobia response toward closely related predator cues (via odor) and avoided these new predators, but they did not produce a neophobia response to distantly related predator or nonpredator cues (Chivers et al. 2016).

Finally, with repeated exposure to the same new stimulus without negative consequences, neophobia changes over time, termed habituation or attenuation. Examples have been provided above in various sections for food and object neophobia that eventually leads to approach and

sampling of the novel food in case of food neophobia or approach and continuation with other activities close-by, e.g., eating familiar food or entering nest boxes in case of object neophobia. However, prolonged absence of the now familiar food or object reinstates the initial neophobic reaction. Examples in birds show that object neophobia is fully reinstalled after a period of 1 month, whereas in tadpoles, predator neophobia wanes after a few days when kept in low-predator regimes.

## Conclusion

Neophobia is an important mechanism to protect organisms from danger and has far-reaching consequences how animals interact with unfamiliar situations. It differs between species as an adaptation to the riskiness of the environment and can also be modulated via learning according to local risks. Neophobia is context-specific and different brain areas are involved in different types of neophobia. Neophobia is often considered a personality trait and as such often consistent within individuals but at the same time differs between individuals and can form behavioral syndromes with other behavioral traits. Finally, neophobia affects cognitive processes how organisms learn about their environment which can affect their ability to respond to environmental change.

## Neoteny

Madeleine K. Meehan and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

Juvenilization; Paedomorphism; Paedomorphosis

## Definition

Neoteny is the deceleration of the rate of somatic development, resulting in paedomorphism (or paedomorphosis).

Neoteny is the deceleration of the rate of somatic development, resulting in paedomorphism (or paedomorphosis). Paedomorphism is a form of heterochrony characterized by the retention of ancestral juvenile traits in descendent adults (McNamara, 2012). Paedomorphism can be the result of neoteny or progenesis (acceleration of sexual development) and it is important to distinguish whether apparently juvenile reproduction is better explained by neoteny or progenesis. The term “neoteny” was introduced by German zoologist Julius Kollmann (1885) to describe the retardation of physiological development in species of amphibians that results in the retention of larval traits in sexually mature adults (Gould, 1977). In neotenic animals, growth and sexual maturation progress but with certain arrests in physiological development.

Neoteny is arguably demonstrated in many modern animals such as species of gobies, termites, mayflies, cicadas, crustaceans, jellyfish, and the Mexican axolotl (*Ambystoma mexicanum*) (Skulachev et al., 2017). An axolotl is an aquatic salamander that retains its gills and remains in water throughout its life. Most salamanders have an aquatic larval stage and emerge from the water as metamorphosed terrestrial adults capable of reproduction and with lungs instead of gills, whereas axolotls reproduce while exhibiting features characteristic of juvenile salamanders (Ridley, 2003). The age at which an axolotl reproduces is not abnormally early for a salamander, suggesting that axolotl age of reproduction remained consistent with non-neotenic salamanders while somatic development slowed down – evidencing neoteny rather than progenesis (Ridley, 2003). Other amphibians display features of neoteny similar to the Mexican axolotl, including the olm (*Proteus anguinus*) and the American mudpuppy (*Necturus maculosus*); however, debate is ongoing as to whether these features are the result of neoteny, progenesis, or both (Wakahara, 1996). Similarly, research has not yet identified the mechanistic basis of neoteny in axolotls, and outstanding questions remain about the functions of variations in salamander life history strategies (Crown et al., 2019).

Although the etiology and function of neoteny in axolotls remains unclear, research indicates that neoteny evolved in various nonhuman animals to facilitate coexistence with humans as a result of artificial selection. Neoteny is a feature of the domestication syndrome, and many neotenic mammals are domesticated. Common physical and behavioral traits of domestication in mammals (and animals, more generally) were identified by Darwin (1868) and include reduction of body mass, shortening of the face, smaller tooth size, reduced sexual dimorphism because of feminization, and reduced skull volume (Wrangham, 2019). Humans have selectively bred animals for docility, and Belyaev (1969) demonstrated that selection for lowered propensity for aggression in foxes produced a suite of phenotypic traits characteristic of neoteny and domestication syndrome such as smaller jaws, skulls, and teeth

(Wrangham, 2019). Exemplary features of neoteny visible in many domesticated mammals are thus the unintended downstream consequence of artificial selection for docility. Animals such as dogs, cats, fancy rats, hamsters, ferrets, and rabbits exhibit neoteny related to the domestication syndrome produced by selective breeding by humans. Natural selection presumably contributed to the development of the domestication syndrome and neoteny in these species since coexistence with humans affords survival and reproductive benefits, such as access to human food and shelter.

Bonobos also demonstrate neoteny related to the domestication syndrome, likely a result of sexual selection. Bonobos evolved from a shared ancestor with chimpanzees between one million and 1.8 million years ago and, despite many shared features, appear to demonstrate the domestication syndrome whereas chimpanzees do not (Wrangham, 2019). Adult bonobos exhibit physical and behavioral similarities to juvenile chimpanzees, suggesting that bonobo development is delayed or occurs at a slower pace than in chimpanzees. Compared to adult chimpanzees, sexually mature bonobos have thinner limb bones, smaller teeth, and narrower faces (Wrangham, 2019). Bonobo females do not face the feeding competition from gorillas that chimpanzee females face and are therefore able to form alliances with other females to dominate an aggressive male and prevent sexual coercion. Female chimpanzees are routinely subject to sexual coercion and unprovoked attacks apparently related to male control of food sharing (Wrangham, 2019). Female alliances facilitate female mate choice, which appears to be the mechanism by which bonobos self-domesticated. Throughout bonobo evolutionary history, females apparently chose to mate with males exhibiting lowered aggression, leading to the unintended downstream consequence of neoteny.

There is strong evidence that humans exhibit neoteny. When a human is sexually mature, it has the bulbous cranium, small jaw, and flat face of a developmentally immature ancestor (Bogin, 1999). Compared to other primates, adult humans demonstrate neotenous traits such as a lack of

body hair, central position of the foramen magnum (which migrates backward in most other primates), a high relative brain weight, persistence of cranial structures to an advanced age, absence of brow ridges, thin skull bones, small teeth, later eruption of teeth, lactose tolerance into adulthood, and no rotation of the big toe (Skulachev et al., 2017). Other neotenous features in humans include the form of the pelvis, the labia majora in females, prolonged growth, prolonged infant dependency, a long lifespan, and short extremities relative to body size (Skulachev et al., 2017). *Homo sapiens* reaches sexual maturity at a later age than ancestral humans, demonstrating neoteny rather than progenesis (Bogin, 1999). Studies have reported that neotenous features illicit more help, render babies cute, and that neotenized female faces are more attractive (Jones, 1995; McArthur & Berry, 1987; Montagu, 1989). The role of neoteny in human ontogeny and phylogeny is a rich area of research that has produced a wide array of theories and findings.

## Synonyms

Neurons

## Definition

Basic structural and functional unit of the nervous system.

## Introduction

Nerve cells or neurons are the signaling cells of the nervous system. They are involved in the generation of action potential and transmission of nerve impulses across the whole length of the body. Nerve cells are considered as the longest and oldest cell in one's body. Glial cells are the other cells (non-neuronal cells) in our brain, which provide support and protection to these nerve cells (Ganong 2005).

## General Structure

Nerve cells contain all the organelles of a general animal cell (like a nucleus, cell membrane, ribosomes, endoplasmic reticulum, Golgi apparatus, mitochondria, etc.). However, the specialized function of electrochemical signaling in nerve cells is provided by the presence of dendrites and axon, attached to the soma (or cell body)

**Nerve Cells, Fig. 1** Nerve cell (Image adapted from: [https://cnx.org/contents/GFy\\_h8cu@9.87:c9j4p0aj@3/Neurons-and-Glial-Cells](https://cnx.org/contents/GFy_h8cu@9.87:c9j4p0aj@3/Neurons-and-Glial-Cells))

(Fig. 1). The cell body in human nervous system can measure from 10–100 micrometers in diameter. Dendrites are thin and short branch-like structures, whereas axon forms a long tail-like structure which originates from the soma at a swelled point known as axon hillock. Axon is covered by a protecting covering of myelin sheath, which is secreted by Schwann cells (a type of glial cell). Axon ends in numerous small terminal buttons. Nerve impulse moves from axon terminals of one neuron to the dendrite of another neuron via synapse (Baars and Gage 2010).

## Functions of Nerve Cells

Main function of nerve cell is to relay electrochemical signal from/to other cells in the body. The generation of action potential across the membrane of nerve cell is interplay of concentration gradient of sodium and potassium ions inside and outside of the cell. (For more information, see “► Neural Impulse”). The general nerve cells send its signal by firing spikes from the cell body down to the axon to the terminal buttons. At the terminals, neurotransmitter is released from this nerve cell (presynaptic neuron) at synapse to trigger a

postsynaptic potential in the next nerve cell (postsynaptic neuron) (Fig. 1) (de Robertis and de Robertis 2001). The connections of nerve cells and their pattern of interactions with each other are the major study points in cognitive neuroscience.

## Classification of Nerve Cells

Nerve cells have a great variety of shapes, branching patterns, and synapses. They can be classified into different ways:

- (a) On the basis of polarity:
  - (i) **Unipolar**: Axon or dendrite (either of them) emerges from the soma
  - (ii) **Pseudo unipolar**: Axon and dendrite emerge from the same side of soma
  - (iii) **Bipolar**: Axon and dendrite emerge from the opposite ends of soma
  - (iv) **Multipolar**: One axon and many dendrites emerge from the opposite ends of soma
- (b) On the basis of direction of neurotransmission:
  - (i) **Sensory**: conduct neurotransmission from tissues/organs to the brain, also known as afferent neurons

- (ii) **Motor:** conduct neurotransmission from brain to the tissues/organs, also known as efferent neurons
- (iii) **Association:** Nerve cells which connects sensory and motor neurons, also known as interneurons
- (c) On the basis of their firing pattern:
  - (i) **Tonic:** constantly active in discharge pattern
  - (ii) **Phasic:** fire in bursts or phase
  - (iii) **Fast:** rapidly fire with a fast rate
- (d) On the basis of their neurotransmitter:
  - (i) **Glutamatergic:** produce glutamate
  - (ii) **GABAergic:** produce gamma amino butyric acid
  - (iii) **Cholinergic:** produce acetylcholine
  - (iv) **Dopaminergic:** produce dopamine
  - (v) **Serotonergic:** produce serotonin
- (e) On the basis of myelination:
  - (i) **Myelinated:** axon is covered by myelin sheath
  - (ii) **Nonmyelinated:** axon is not covered by myelin sheath

## Neurons and the Nervous System

Neurons or nerve cells feature specialized *elongated structures* that allow for high speed

(up to 100 m/s or 223 mph) transmission of signals via electrical impulses (action potentials) from receptor sites or other neurons to effectors or other neurons (Ramon y Cajal 1906). These elongated structures (or processes) are known as dendrites (branched structures) and axons (long fibers some of them can extend along the length of the body), together called neurites. The Nervous System (NS) is an organized network of neurons that transmit signals between different parts of the body to generate adaptive responses. In many animal NSs, neurons are accompanied by a specialized class of cells, called glia. Glial cells support and protect neurons, in addition to wrapping processes of their own in a sheath-like manner around neurites for insulation and better propagation of action potentials. NSs can be found in all animals except the placozoa and porifera phyla, which lack neurons.

In early evolved animals, neurons form diffuse networks, referred to as nerve nets, mainly associated with the body wall. In some of these animals, neurons tend to be clustered around sensory structures and the sites of higher physiological activity – forming round shape neuronal conglomerations referred to as ganglia (singular: ganglion), and elongated structures called nerve rings or nerve cords. The centralized NSs of bilaterians are likely to have evolved from such local clusters of neurons. With the rise of bilateral animals, sensory organs better coordinate the two halves of the body concentrated in the anterior end of the body (head). The brain formed around these sensory structures by concentration of ganglia involved in receiving and processing sensory input. This organization often divides the NS into two parts: the brain and the associated nerve cord extending throughout the body form the Central Nervous System (CNS), and the peripherally located sensory neurons, nerve nets, and the nerve fibers (axons) communicating between the CNS and the periphery form the Peripheral Nervous System (PNS).

## Nervous Systems of Invertebrates

Invertebrates being the most extensive and diverse group of animal life (comprising 90% of all existing animals) have evolved with a variety of NSs.

Cnidarians (hydra, sea anemones, and corals) are the earliest animals with NSs, organized as nerve nets. The cnidarian body is formed along an oral-aboral axis with two layers of tissues. The epidermal (outer) layer forms skin, while the endoderm (gastrodermis or inner layer) forms the gut, and nerve nets are sandwiched between them and form the NS (Davis 1974). This is a basiepithelial NS, separated from the interior of the animal by the epidermal basement membrane. The NS is composed of sensory and ganglion neuronal cells. They form chemical synapses with both epithelio-muscular cells and neighboring neurons – performing both sensory and motor functions, which in higher animals are performed by two different neuron types. Neurons conglomerate near the mouth, foot, and base of the tentacle. In many hydra species, sensory neurons condense at the opening of the mouth forming a nerve ring. Some cnidarians have light- and gravity-sensing organs called ocelli and statoliths respectively at the bases of marginal tentacles. They may be integrated into larger sensory organs called the rhopalialia. The ocelli contain ganglion-like clusters of light-sensitive neurons, connected by nerve tracts to the nerve rings of the bell margin, where the signals are integrated and transmitted to the motor neurons (muscles) to control the pace of swimming by muscle contraction.

The phylum Platyhelminthes (class Turbellaria) comprises unsegmented, soft-bodied flatworms, commonly known as planarians, which are phylogenetically close to cnidarians. They represent the most primitive known extant animals exhibiting a bilateral symmetric body layout common to vertebrates and many invertebrates, and an anterior concentration of sensory organs in the head (cephalization), including a pair of simple eyes. Flatworm NSs are composed of a basiepithelial nerve net which innervates the ciliated epidermis,

bilobed anterior ganglia (brain), and bilaterally symmetric nerve cords (Morita and Best 1966). The neurons forming the brain ganglia and nerve cords are separated from the epidermis by a basement membrane and concentrated within the body cavity. Their cell bodies encircle their neurites and synapses called the neuropil. The outer layer of cell bodies is called rind (in invertebrates) or cortex (vertebrates). This organization is called subepithelial NS. The cell bodies of the brain are intermingled with the neurosecretory cells and accessory cells that resemble neuroglia. The nerve fibers of the neuropil are closely packed, mostly unmyelinated, and terminate in close contact with endings of other nerve fibers to form synapses. The nerve fibers emanating from the brain are initially arranged into tracts, and then cables of parallel fibers, and extend in a caudal direction to form the longitudinal nerve cords along the length of the body. The two largest ventral nerve cords ensure rapid signal conduction from head to tail. They further extend as peripheral nerve fibers to form subepidermal and submuscular plexuses throughout the body – resembling two sides of the vertebrate spinal cord. There is a closer resemblance of these neurons to the neurons of vertebrates than to those of higher invertebrates, even though the glial sheath is absent. Planarian neurons are multipolar with a single axon, excessive dendritic branching, the presence of dendritic spines, and the predominance of chemical synapses compared to electrical ones. These features are rarely observed even in higher invertebrates but are reminiscent of the vertebrate brain. Therefore, planarians are considered a living example of the early evolutionary stages of the vertebrate brain.

Adult *Caenorhabditis elegans* hermaphrodites (phylum nematoda) are composed of exactly 959 cells, 302 of which are neurons that belong to two distinct and independent NSs known as somatic (282 neurons) and pharyngeal (20 neurons) (White et al. 1986). The somatic NS is also supported by 56 nonneuronal cells called sheath cells, socket cells, and GLR cells. These NSs communicate through a single pair of ring-pharynx interneurons. The neurons of somatic NS and their neurites are mainly positioned

between the hypodermis and the hypodermal basal lamina that separate them from the body wall muscles. In contrast, the neurons of pharyngeal NS are positioned directly along the pharyngeal muscles. Several head ganglia surrounding the pharynx constitute the bulk of neurons and form a brain of basiepithelial type. Most of them are sensory neurons (69 in total) that detect various soluble volatile chemicals, tactile stimuli, and temperature. The brain neuropil encircles the axially placed esophagus, associated cells, and center of the pharynx isthmus and forms a nerve ring. Neurites of sensory and interneurons form synapses as they run next to each other in the nerve ring. Sensory neurons extend their dendrites to the sensory organs such as sensilla, while their axons join the nerve ring, where they form synapses with interneurons. Some neurons also extend their long axons along the ventral cord, which runs the entire length of the animal. Motor neurons are scattered around the ventral nerve cord and innervate muscles allowing the animal to respond to sensory input by changing its movement pattern. Sensory organs called sensilla (singular sensillum) are composed of dendrites from one or two bipolar sensory neurons surrounded by a glial-like single sheath cell and one or more socket cells. Sensilla are predominantly situated in the head and the tail of the animal. Sheath cells envelop neurons' endings, and some part of the neuropil and ventral cord.

Arthropods have a segmented body in an exoskeleton with paired, jointed limbs at all or several of the body segments. Arthropods possess subepithelial NSs with an anterior brain, and a series of ventrally located ganglia in most body segments making up the ventral nerve cord running down the abdomen. These ganglia appear physically fused (but are connected by commissures) at the midline in pairs in bilateral symmetry, and their lateral nerves innervate each side of the body segment and/or appendages. Most arthropod brains (called supraesophageal ganglion) are formed by three dorso-anteriorly paired ganglia in the head segments. The subesophageal ganglion, another fused complex of ganglia, lies ventrally in the head, just below the brain, and

innervates mouthparts, salivary glands, and some muscles. In posterior direction, it is followed by the thoracic, abdominal, and specialized terminal ganglia. The thoracic ganglia innervate appendages and control walking and flying-like activities. The abdominal ganglia innervate pleopods, reproductive organs, and anus, and control several activities including swimming. Each ganglion can process sensory information in its own body segment and pass it on to neighboring ganglia without input from the brain. Sensory neurons are mostly located outside ganglia in the periphery (integument) and constitute the PNS. The longitudinal compression of ganglia is a common variation in arthropod NSs. For example, brain and thorax ganglia are compressed as a single unit in scorpions, locusts, and lobsters and are called synganglion. The arthropod brain has three anatomic divisions. The protocerebrum is a pair of ganglia in the foremost head segment, which innervates vision-related sensory structures (compound eyes and ocelli). In some social insects such as bees and ants, the protocerebrum contains thousands of specialized neurons called mushroom bodies (Ito et al. 1998). They are the centers of higher-order sensory integration involved in sophisticated learning and decision-making. The deutocerebrum innervates antennae, labial palps, and parts of the tegument (body wall) and controls chemo-sensation and tactile sensation. The tritocerebrum innervates the labrum and integrates sensory input from proto- and deutocerebrum, in addition to linking the brain to the rest of the ventral nerve cord.

Mollusca phyla have the most intriguing invertebrate NSs, which comprise a subepithelial CNS, and basiepithelial peripheral nerve nets. Most molluscan NSs are composed of (five to) six paired ganglia. Sensory and motor information from the sensory organs is processed by the largest and most lobed anterior cerebral ganglia. The buccal ganglia innervate the muscular feeding organ, called the buccal mass, and control eating-related activities. The pedal ganglia control locomotion and conjoint muscle movements involving the shell in snails. The pleural ganglia supply nerves to the mantle cavity, and their functions are generally unknown. The abdominal/parietal ganglia innervate internal

organs. Many complex actions that require the integration of whole-body movement involve more than one ganglion.

Some molluscan NSs have remarkable features. For example, the *Aplysia* (class gastropoda) NS is composed of 20,000 neurons arranged in four pairs of head ganglia and a single abdominal ganglion (Kriegstein 1977). Some of these neurons represent the largest nerve cells in the animal kingdom (up to 1 mm) and can be seen with the naked eye. Their giant size makes a single neuron an extremely powerful center in controlling multiple complex behaviors and tasks. Cephalopod NSs are the largest of all invertebrates. Their brain-to-body weight ratio exceeds that of most fishes and reptiles. Octopuses are among the most intelligent and behaviorally diverse soft-bodied invertebrate animals, with excellent vision, and a mouth located at the center point of eight highly efficient, flexible limbs (arms). The CNS is composed of the brain and optic lobes that contain about 40 and 130 million neurons, respectively. The brain size surpasses many vertebrate brains in terms of cell number and complexity. The PNS consists of two-third (~350 million) of the total neurons located in the body and arms (Gray and Young 1964). Most neurons are organized in the nerve cords and ganglia of the arms and act as lower motor centers to coordinate the movements of arms and suckers. The ganglia of head and trunk are fused into one large brain around the esophagus and anatomically divided into a supraesophageal and a subesophageal part, connected laterally. Each of these parts is further subdivided into a varying number of lobes depending on the Cephalopod species. Almost all brain nerves project to, and/or originate from, more than one of these lobes, and almost all lobes, including the subesophageal lower motor centers, have two-way connections. Therefore, many of these lobes (the supraesophageal ones in particular) do not have a single precise function.

Octopuses have a large number of chromatophores distributed across their entire skin. Each chromatophore consists of a membranous sac containing a pigment, which can be red, yellow, brown, or black in color. Each pigment sac is

surrounded by about 15–25 radial muscle cells. When the muscles contract, the sac expands, and the color becomes visible on the octopus' skin. Conversely, the respective pigment becomes less visible when the muscles relax, and the pigment sac shrinks back to its original size. These muscles are controlled by nerve fibers projecting directly from a brain region called chromatophore lobe. The muscle fibers form synapses with glutamatergic motor neurons. Historically, it was this synaptic connection where the neuromodulator action of acetylcholine and serotonin was first demonstrated (Messenger 2001). Perhaps, this Cephalopod neuromuscular image generation system is the only example of chromatophores in animal kingdom, which is neuronally controlled and allows for an unprecedented, fast, localized change in body color, which is often used to trick prey and confuse predators. Octopus arms can, without bones, move in infinite directions. The arm movement is controlled by higher motor centers in the brain, which send global commands to the neuronal centers in the arm. These then control the entire spatiotemporal details of the movement. The arm NS is extensive and works independently. Many cephalopods also have giant nerve fibers for achieving extremely fast conductance of action potentials for the rapid activation of the mantle muscles during jet-propelled escape.

Lancelets (amphioxus) and tunicates are the only two groups of invertebrates belonging to the Chordata phylum. Tunicates NSs have an invertebrate layout consisting of ganglia with nerves that innervate siphons, mantle, and muscles. Amphioxus is the closest living relative of vertebrates with a similar body and NS plan. The amphioxus CNS consists of a hollow dorsal cord that closely resembles the vertebrate NS. Amphioxus has a cerebral vesicle that shows some similarity to vertebrate brains. *Nervous System*, and ► [Vertebrate Nervous System](#) chapters describe such NSs in detail.

In summary, invertebrate NSs consist of nerve nets, ganglia, and nerve cords with a variation in organization across species. Ganglia of considerable size at the anterior (or head) end of the body in many invertebrate species can be considered a

primitive brain. Molluscan NSs evolved with remarkable unique features.

## Introduction

Living organisms sense the changes in the external environment and respond accordingly to maintain homeostasis. The survival of organisms depends on how they sense and respond to their surroundings. The quicker the responses, the better the chances of survival. Early in evolution, animals acquired a system which helped them to integrate multiple sensory inputs and produce directed responses at a speed of hundreds of kilometers per hour. This system is referred to as the nervous system (NS) – an organized network of cells having processes extended throughout the body, which can sense external cues and direct responses from simple voluntary or involuntary movements of the body to managing emotions or solving complex survival problems. Even simple NS of primitive animals have staggering complexity in the way they process information, store it, and decode it based on the stimulus. Humans have a marvelously complex NS, which allows us enormous cognitive capacity and helped us to conquer every part of the planet and beyond.

## Fundamental Units of the Nervous System

The NS is a diffused or centralized network made up of a specialized cell called neuron and its projection in every part of the body, often supported by another specialized cell called neuroglia.

### Neurons

Neurons evolved with the ability to engage in electrical communication with each other. Each neuron has three specialized structural parts, which are called dendrite, soma (also called cell body, plural somata), and axon (Fig. 1). Dendrites are projections of the soma which receive signals from other cells and transmit to the soma (in many cases, directly to the axon). The soma contains typical subcellular organelles found in eukaryotic cells. It processes and transmits signals along the axon. The axon is a single long fiber branched into fibrils at its distal end. The terminal end of each fibril has a bulb-like structure called synaptic knob, which contains synaptic vesicles filled with chemicals called *neurotransmitters*. The axons projecting from the somata can run through the length of the animal's body in a bundle called fiber, and multiple fibers form a nerve trunk. The function of an axon is to carry signals away from the soma toward an anatomical site referred to as the *synapse* or to a neuromuscular junction (Golgi 1906; Ramon and Cajal 1906). The synapse is the region formed between the membranes of two neurons (called pre- and postsynaptic neurons), which may or may not be separated by a fluid-filled small space called synaptic cleft (Fig. 2).

Neurons are divided into three major groups: sensory, motor, and interneuron, based on the way they communicate among themselves and with other cells. Sensory neurons typically have a long dendrite and short axons and carry signals from sensory receptors to the NS. Motor neurons have a long axon and short dendrites and transmit signals from the NS to a muscle or to a gland. The third type of neuron is called interneuron or short-axon neuron, found only in the central NS where they connect with projecting neurons.

**Nervous System, The, Fig. 1 A general structure of a neuron and its types.** The cell body receives signals via converging dendrites. The axon, a cylindrical elongation of the cell body, conducts action potentials out of the cell via synaptic terminals and releases neurotransmitters into the synaptic cleft influencing other neurons. Each dendrite contains spines which increase the contact surface in order to form synaptic contacts. The tip of the dendrite is a highly active site for protein synthesis due to the high concentration of ribosomes as compared to the rest of the neuron. The dendritic extensions are usually variable, decreasing in diameter, but axonal extensions, also

known as axis cylinders, have uniform diameters and branched terminations that make contact in a region-dependent way with nerve, muscle, glandular cells, etc. The axon can span a few hundred micrometers or much longer distances. For example, neurons of the spinal cord have very long axon projections, while very short ones are part of local circuits in the brain. The branched end of the axon dilates to form the synaptic buttons or terminals. These participate in the communication either through electrical activity or through neurotransmitters. Nine common types of neurons can be observed (right panel)

Axons can be wrapped by several glial cells disposed side by side. The spaces between these cells on axons are known as the *nodes of Ranvier* and facilitate signal conduction along the axon. Nerve impulses jump from one node to another traveling hundreds of times faster than impulses traveling continuously along the surface of the axon. Neurons can be further classified based on different criteria such as their function, activity, location in the body, electrochemical properties, and morphology, including the axonal and dendritic patterns (Fig. 1).

### Neuroglia or Glial Cells

In many animal groups neurons are accompanied by a second class of cells, called glia or neuroglia. Glial cells nourish, support, and maintain neurons

as well as form sheath-like processes around neuronal cell bodies and nerve fibers. Glial cells are of four types – oligodendrocytes, Schwann, microglia, and astrocytes. Oligodendrocytes and Schwann cells produce a layer of a fatty substance called myelin in the central and peripheral nervous systems respectively. Myelin wraps around axons, providing electrical insulation that allows neurons to transmit nerve impulses much more rapidly and efficiently. Microglia and astrocytes may also act as resident immune cells to protect the brain since the cells of the dedicated immune system usually cannot cross the blood-brain barrier (Hickey and Kimura 1988). These cells are involved in phagocytosis during development, and in the mature and diseased NSs. Glial cells also provide guidance cues for directing the axons

**Nervous System, The, Fig. 2** Diagram of signal transmission between neurons. The upper part shows two cells communicating by a chemical synapse. The presynaptic neuron releases neurotransmitters as a result of an action potential entering its axon terminal. In response to binding neurotransmitters, the post synaptic neuron discharges a new action potential. In the lower part, excitatory and

inhibitory synapses are exemplified. Glutamate is an amino acid which serves as the most common excitatory neurotransmitter in the mammal CNS. Gamma-aminobutyric acid (GABA) is the most abundant neurotransmitter present in mammalian inhibitory synapses. Ion channels participate in changing the membrane potential in both excitatory and inhibitory synapses

N

to their targets or extending branched processes that interact with terminal nerve fibers and synapses. Hence, they play a critical role in development and the establishment of neuronal signal transmission. The total number of human glial cells is roughly proportional to the number of neurons present in the brain. The proportions may vary in different areas of the brain, indicating that glial cells play pivotal roles, as neurons do, in shaping the brain structure and nerve responses.

## The Signal Transmission Between Neurons

In metazoans, neurons evolved as specialized cells capable of conducting electric signals, also termed nerve impulses, enabling neurons to

communicate between each other (Hodgkin et al. 1952). Like any other cell, neurons maintain different concentrations of certain ions across their membranes. Ions that are important in building nerve impulses include sodium and potassium. More positively charged ions flow out of the neuron than those which flow inward. This imparts a positive charge on the outside of the neuronal membrane and a negative charge inside. It creates a voltage difference across the membrane referred to as the membrane potential, and the membrane is said to be polarized. Neurons are said to be at rest when they are not conducting a nerve impulse. The resting potential of a neuron is approximately  $-70$  mV, during which the neuron has an overall negative charge. Membrane potential is transiently modulated by electrochemical signals from nearby cells. The fast and temporary

reversal of the membrane potential is called the action potential. This takes place extremely rapidly, in about 0.002 s, thus allowing neurons to fire action potential in series, a common feature in neuronal communication or signal transmission.

Since the cell membrane is almost impermeable to ions, there are two types of specialized proteins located on the membrane of a neuron, which allow selective passage of ions to maintain the membrane potential. They are called sodium-potassium ATPase pumps (or ion pumps) and ion channels. The transport of ions through a cell membrane against their concentration gradient requires energy expenditure since ions have to be transported against their flow. Ion pumps are equipped with ATPases which break down ATP molecules to generate the energy required for the transport. In contrast, ion channels transport ions along their natural flow in favor to the concentration gradient, hence not requiring energy for this process. Ion channels are highly specialized to the specific type of ion they transport. Ion pumps and channels are usually closed, but they open in response to differences in ion concentrations across the membrane. Sodium channels respond to slight membrane depolarization and, once they are open, allow a quick influx of sodium ions, thereby switching the resting potential. The membrane is depolarized locally, and this depolarization triggers the opening of adjacent ion channels. Thereby, the impulse of an action potential spreads across the neuronal membrane and along the axon. In order to restore the net electrical charge across the membrane, potassium channels open to release potassium into the extracellular milieu. Both channels close after the action potential has passed. Ion pumps then work continuously to transport ions back to their respective locations against their concentration gradients to restore the original resting membrane potential and ion concentrations.

Action potentials spread anterogradely, away from the soma, because once the ion channels close, they cannot be opened again for a short time called refractory period and will be opened again only by an extraordinarily strong depolarization during this period. Not only does this mechanism ensure directionality of the impulse, but it also determines the maximum frequency

at which nerve impulses can be passed down the axon.

Nerve impulses generated by an action potential are transmitted from one neuron to another through synapses (Fig. 2). The nerve impulse may directly transmit from one neuron to another through a synapse when they are close to each other leaving no room for synaptic cleft formation. Such synapses are called electric synapses. In this case, neurons electrically excite other cells by the changes in the membrane potential elicited by the passage of ions and small molecules through the specialized proteins linking their membranes at synapse (Hodgkin et al. 1952).

Nerve impulses may also be transmitted indirectly when neurons are farther apart, forming a synaptic cleft at the synapse between them. This type of synapses are called chemical synapses. In this case, the nerve impulse crosses the synaptic cleft with the help of neurotransmitters that are small molecules or ions stored in small synaptic vesicles clustered at the tip of the axon (Dale et al. 1936). When an action potential increases, some of the vesicles move to the axonal membrane and discharge their contents into the synaptic cleft via exocytosis. Neurotransmitters therein diffuse across the cleft and bind to their specific receptors on the next cell, causing ion channels on that cell to open, thereby transmitting or interfering the nerve impulse along the membrane. Neurotransmitters released in the synaptic cleft are active only for a short period of time. They are either inactivated or broken down by specific enzymes in the cleft or reabsorbed into the axon of the cell which released them for recycling. Neurotransmitters are generally small (often amino acids), and some are even hormones. Neurotransmitters act in between 0.5 and 1 ms; some trigger an action potential, while others inhibit it.

## Embryonic Development of the Nervous System

In the course of animal embryonic development, a single fertilized egg cell undergoes division to form a sphere of cells called blastula that differentiates into layers of cells called germ layers.

Animals with just a single layer of germ cells (homoblastic) evolved early on, followed by animals with two (diploblastic) and three (triploblastic) germ layers. In diploblastic animals, the inner layer of cells is called endoderm, and an outer layer is called ectoderm. In triploblastic animals, a third germ layer called mesoderm develops between endoderm and ectoderm. The process of germ layer formation is called gastrulation and exists perhaps in all animals except in sponges. These germ layers differentiate into various organs as the embryo develops.

Of the three germ layers, the ectoderm (in some animals the endoderm) gives rise to the NS during embryonic development. Some regions of the ectoderm express specific transcription factors influenced by the signaling molecules (morphogens) secreted by nearby embryonic cells. These transcription factors are called neural determinants, and the ectodermal region where they are expressed is called neuroectoderm. In these regions, neuroectodermal cells are maintained in the proliferative state. These cells then express a second set of transcription factors to become neural progenitor cells. These progenitor cells proliferate, migrate, and differentiate in a stereotypic pattern along the gradients of morphogens and neural determinants to form various parts of the NS.

The embryonic development of the NS is tightly regulated spatio-temporally by a gene expression program influenced not only by intrinsic determinants from within the developing NS but also by extrinsic determinants from other regions of the developing embryo. The genetic mechanisms underlying neural progenitor specification and formation of neurons are fairly similar among all the well-studied model organisms.

## Evolutionary Origin of the Nervous System

Animals have a relatively recent evolutionary origin compared to remaining living organisms. They are likely to be evolved from a group of free-living, single-celled, colonial choanoflagellate-like eukaryotes having a sophisticated toolkit for

sensing and responding to the environment. Early evolved animals have been placed in four major groups, Porifera (sponges), Placozoa (flat animals), Ctenophora (comb jellies), and Cnidaria (hydra, corals, and sea anemones). The phylogenetic placement remains contentious for these groups.

Porifera and Placozoa taxa branched off the phylogenetic tree at an early stage of animal evolution. Neurons and synapses are absent in extant members of these groups. Ctenophores and cnidarians have neurons and synapses, which constitute a simple, diffused NS. There are two schools of thought on the origin of neurons in these phyla (in other phyla too). Traditionally, it was thought that neurons have monophyletic origin – the primordial neuron evolved into all neurons found in extant animals. Current molecular evidence, however, suggests that neurons evolved multiple times. For instance, neurons in ctenophores and cnidarians may have independent origin. The assumption here is that the molecular building blocks of neurons, such as ion channels, ion pumps, neurotransmitters, and vesicular transporters, can be found in choanoflagellates, sponges, and placozoa. Neurons could have possibly evolved from the cells having these building blocks just by rearranging certain components of their cytoskeleton to form elongated processes. This event could have happened multiple times during animal evolution.

A significant step toward the centralization of the NS from a diffused network took place approximately 700–600 million years ago with the appearance of the bilateral symmetric animals. The ancestral cnidarians are likely to have branched off from the other animals, and some animals evolved with bilateral symmetry. Bilateral animals are triploblastic and include all organisms from tiny worms to humans (Fig. 3). Their NS is characterized by two major components – the central and the peripheral. In many cnidarians and ctenophores, regions of higher neuronal density are detected at the mouth opening and at the base of tentacles. Such conglomerates of neurons can take a rounded shape to form ganglion (plural, ganglia) or elongated structures to form nerve rings or nerve cords. It is likely that

**Nervous System, The, Fig. 3** A timeline tree depicting the evolution of the nervous system and its components.

The phylogenetic tree was created using representative species of each of the lineages shown in the figure. The position of each taxon in the tree is based on the morphological and molecular data available to date. The positions of lineages that diverged before cnidarians are contentious. First neurons are likely to have appeared in the ancestors of

ctenophores and cnidarians, with simple NSs in the form of nerve nets. Bilateral symmetric animals were then branched off from Cnidarians and evolved with nerve cords, agglomerates of sensory structures in the ventral side of the body, and the brain. Cephalochordates have a notochord in addition to a brain. Eyes and most olfactory systems evolved in ancestors of fish and also spinal cords. An enlargement of the brain occurred in mammals

from such local densities or ganglia, true centralized NSs evolved in bilateral animals.

The bilateral animals have defined top, bottom, front, and back. The appearance of bilateral animals followed an evolutionary trend, which is called cephalization. It means the concentration of the neurosensory organs at the anterior end of the body formed the head and the brain during evolution. Flatworms are the most primitive bilaterians and belong to the Platyhelminthes phylum of unsegmented, soft-bodied invertebrates, which are phylogenetically close to cnidarians. Platyhelminths are the first animals of organ-grade construction with an anterior concentration of neurons and sensory systems, accompanying the first signs of cephalization. They are also the first animals to have a true centralized NS, which

constitutes a ganglionic mass in the head of the animal as a sort of primitive brain. There are multiple paired nerve chords that extend from the ganglia along the length of animal body. Flatworms serve as the basal stock from which all higher animal phyla are thought to have evolved. In some more evolved invertebrate bilaterians, particularly within the nematode, annelid, and arthropod phyla, ganglia are segmented anteriorly with the nerve cords running down the ventral plane of the body (i.e., bottom side of the body as opposed to back).

Chordates evolved with a more elaborate NS which includes a dorsal NS rather than a ventral one, continuation of cephalization in the form of larger and more complex brain, and appearance of the characteristic feature defining

the phylum – the notochord, which provides physical support for the development of NS in the embryo. More specialized brain regions arose with the appearance of vertebrate animals – characterized by the presence of vertebral column containing neurogenic tissue outside of the brain called the spinal cord.

The fossils from the beginning of the Precambrian period provide potential reasons for the evolution of complex NS in animals. Animals likely evolved with fast-conducting systems like neurons for keeping different parts of the body coordinated and making quick movements to obtain food and to avoid predators.

## The Architecture of the Nervous System

NS organization is diverse in modern animals. The simplest NS can be found in early evolved cnidarians and ctenophores. Cnidarians are important for understanding the evolution of the NS since most phylogenetic criteria place them at the base of bilateral animals. They have a radially symmetric body formed around an oral-aboral axis by two tissue layers. An outer layer, the epidermis, forms the skin, and an inner layer, the endoderm (gastrodermis), forms the gut. The network between the epidermis and the endoderm is similar in structure to a cobweb and is referred to as the *nerve net*. A cnidarian polyp typically has several independent nerve nets, which tend to be condensed near the mouth opening forming a nerve ring in adults. There are two types of neuronal cell types found in a nerve net called sensory and ganglion neurons. The ganglion cells connect different neural structures within the NS. Sensory cells detect different stimuli such as light, touch, or temperature. Davis and Koizumi et al. carried out a detailed anatomical study of the nerve nets and rings of *Hydra* (Koizumi et al. 1992; Davis 1974). The nerve net is associated with the inner or basal side of epithelial/epidermal layer of the body wall, with no signs of centralization. The nerve net-based NSs can also be found in ctenophores and echinoderms. All these animals are characterized by a radial symmetric body around a central digestive cavity.

## The Nervous System of Animals with Bilateral Symmetry

In early bilateral animals, the conglomerates of neurons (ganglia) began to cluster around sensory organs (near the mouth and primitive eyes) in the anterior part of the animal – forming the first brain-like structure – the sign of cephalization, enabling animals to move and respond to the environment in even more sophisticated ways. When neurons are clustered their cell bodies form a processing center, and nerve cords running through them can innervate various parts of the body to receive sensory inputs. In this way, information could be further processed rather than merely relayed as in the case of nerve nets. Many biologists suggest that the last common ancestors of bilateral animals – probably worm-like animals – had such a primitive brain. The presence of regions with higher neuronal density in cnidarians supports this notion. The brain and the nerve cords form the central nervous system (CNS). The nerve net and/or sensory neurons located in the periphery, and the nerve fibers communicating between the CNS and the periphery, constitute the peripheral nervous system (PNS).

NS is further organized between bilateral animals that are vertebrates and invertebrates. The major notable difference between vertebrate and invertebrate NSs is the degree of centralization.

In invertebrates, the CNS constitutes an aggregation of neuronal components organized into longitudinal or ring-like nerve chords usually near the midline of the body. A planarian (Platyhelminthes) has two nerve cords running along the length of its body from the two ganglia at its anterior end. Likewise, two nerve cords are fused and run down the ventral surface of the body in earthworms belonging to annelid phyla. Arthropods such as the crayfish also have a double ventral nerve, in addition to ganglia in the head. Some organisms have more than one nerve cord connected by transverse nerves, resembling a ladder.

In many invertebrates such as annelids, arthropods, and molluscs, a CNS and a PNS can be distinguished. In these animals, a series of ganglia are usually located along the animal's midline. The peripheral component of the NS is formed

by the extensions of the cells in the ganglia. Some of these cells carry sensory information from the environment to the ganglia, while others carry signals from the ganglia afferently to produce a response (such as movement). Each ganglion along the midline responds to, and controls, an individual segment of the body. Ganglia connected to each other coordinate the segments in a chain-like fashion by a nerve cord, which runs throughout the length of the body. The nerve cord is enlarged at the anterior (or head) end in many invertebrates and can be considered a primitive brain. In squids (molluscs), this primitive brain enables visual information processing and rapidly generates coordinated responses in order to escape or capture preys. This invertebrate NS is so specialized that it closely resembles some vertebrate NSs. Two groups of invertebrates, the tunicates and the lancelets (protochordates), are grouped with the vertebrates as chordate. The NS of an adult tunicate is fairly like other invertebrates in layout, in that it consists of a ganglion

with nerves that radiate out to innervate the siphons, mantle, and somatic muscles. In contrast, the NS of adult lancelet *Amphioxus* is a hollow dorsal cord that much more closely resembles a vertebrate NS. The front end of the dorsal cord clearly has a great homology with vertebrate brain structure. There is also a simple anterior eyespot likely to be homologous with vertebrate eyes. The vertebrate NS is much more centralized and cephalized as compared to the invertebrate NSs and is described in detail below.

## Vertebrate Nervous System

In the vertebrate NS, the CNS and the PNS are clearly defined anatomically. The CNS comprises the brain and the spinal cord, whereas the PNS is formed by ganglia and nerves (Fig. 4). Conventionally, a cluster of neuronal cell bodies within the CNS is called a *nucleus*, while a cluster outside the CNS is called a *ganglion*.

**Nervous System, The, Fig. 4** The organization of the nervous system and its parts in the human body. The central nervous system is composed of the brain and spinal cord (pink). The brain is anatomically organized into the frontal, temporal, parietal, and occipital lobes. The peripheral nervous system (gray) is formed by spinal nerves that arise from the peripheral ganglia (cluster of neurons) and innervate different organs

## The Central Nervous System

The CNS is enclosed and protected by three-layered membranes called meninges. The outer, tough, and leathery layer is called *dura mater*, whereas the delicate innermost membrane layer is called *pia mater*, which is pierced by blood vessels that supply the CNS with oxygen and nutrients. The *arachnoid mater*, a middle membrane layer, provides a cushion between the *dura mater* and *pia mater* layers. In addition to the meninges, the brain is also protected by the skull which houses the brain and certain sensory organs – including the cranial cavity and mandible. Like the brain, the spinal cord is enclosed by meninges and further protected by the vertebrae, a set of interlocking bones that, together with intervertebral discs, form the spinal column. A third mechanism of protection of the CNS is provided by the cerebrospinal fluid, which surrounds the brain in the skull and lies between the spinal cord and vertebrae, thereby offering a buffer to impact in the brain and spinal cord. In addition to these mechanisms of physical protection, the selectively permeable blood-brain barrier further protects the CNS from toxic substances and pathogens (Abbott et al. 2006).

At the tissue level, the CNS is divided into areas of gray and white matter. The gray matter contains a high proportion of neuronal cell bodies and their dendrites, glial cells, and capillaries. The gray matter is mainly composed of clusters of neurons in the brain and spinal cord and in outer layers that line their surfaces. The white matter is mainly composed of myelinated axons and appears white due to the myelin sheaths and scarcity of blood vessels.

The brain controls almost all the processes carried out in the CNS and has three anatomical subdivisions: *prosencephalon* (forebrain), *mesencephalon* (midbrain), and *rhombencephalon* (hindbrain). The forebrain is a frontal part of the brain, which is covered with a large, wrinkly, outermost layer of the brain – the cerebral cortex (Fig. 4). It consists of a left and right hemisphere, each of which is further divided into four major lobes: frontal, parietal, temporal, and occipital lobes. There is a portion of the cerebral cortex folded deep within the fissure separating the temporal lobe from the parietal and frontal lobes. These lobes together constitute the largest site

of neural integration in the CNS and play key roles in memory, attention, perception, awareness, thought, and language.

The midbrain is a vital connection point between the forebrain and the hindbrain. This is the topmost part of the brain stem, which connects the brain to the spinal cord. The upper portion of midbrain has two principal pairs of structures called the superior and inferior colliculi. The superior colliculus processes visual signals before they are passed on to the occipital lobe through the thalamus. The inferior colliculus processes auditory signals before they are passed, through the thalamus, to the main auditory processing center in the cortex.

The hindbrain is the lowest portion of the brain stem, and it is composed of the medulla oblongata, pons, and cerebellum. The medulla oblongata contains cardiorespiratory centers that can increase or decrease the cardiac and respiratory rates depending on the physiological needs. The pons is responsible for conducting signals from the brain to the cerebellum and down to the medulla, and has tracts that carry the sensory signals from the spinal cord up into the thalamus. The small cerebrum, or cerebellum, is a rounded structure hosted in the posterior fossa of the cranium, behind the pons and medulla oblongata, and underneath the occipital lobe. The cerebellum is an integration center which processes sensory information for movement-related functions.

## The Peripheral Nervous System

The PNS is organized as clusters of neurons or ganglia and nerves outside the CNS. Nerves form several branches that innervate every sensory ending of the body, linking them with the CNS (Fig. 4). The PNS is further subdivided into two parts: the somatic and the autonomic. Nerves are also classified as sensory, motor, or mixed nerves if they contain axons from both sensory and motor neurons. Based on the signal transmission, toward or away from the brain, nerves are termed afferent or efferent respectively. The afferent nerves arise from the sensory neurons, which receive inputs from sensory organs, such as the ears, eyes, nose, tongue, and skin, and pass the signal to the CNS. There, nerve impulses are processed to elicit the appropriate sensation. The efferent nerves transmit signals from the CNS to motor neurons and

are responsible for putting the organs and muscles into action to execute voluntary movements of the limbs (Sherrington 1906). The somatic NS innervates the skin, joints, and muscles. It regulates the movement of skeletal muscles. The autonomic NS contains nerves that innervate the internal organs, blood vessels, and glands. It controls involuntary actions such as heart rate, digestion, and perspiration.

## Closing Remarks

The NS is substantially similar within vertebrates, with subtle differences in specialized structures and their functions. However, early evolved invertebrate animals show staggering diversity of NSs, even within various phyla. Despite the complex diversity of NSs across metazoans, their NSs coordinate and control bodily functions in a relatively similar manner. Nonetheless, appearance of NSs in animals bestowed them the ability to respond faster and attentively, which in large part can be attributed to their success on the planet.

Animal Architecture; Nest Building

## Definition

Nests are structures built by animals, typically for the purpose of holding the animal's eggs or live offspring.

There is considerable diversity in nest construction across species. Nesting occurs in a wide variety of species, and there is great variety in how nests are constructed within phyla and even within genera. Dinosaurs built nests that often consisted of simple depressions in the ground, and in which eggs were laid and incubated (Chiappe et al. 2004; Norell et al. 1995). Birds are the living descendants of dinosaurs and, although some living species do construct ground nests (Angelstam 1986; Manolis et al. 2002), there are many different strategies of nest building among the various bird species. As seems to be the case in dinosaur nests, bird nests typically function as structures for keeping eggs, and later chicks, safe from predation (Heenan and Seymour 2011).

Because bird nests function to keep eggs and chicks safe from predation and environmental hazards such as rain, there is a sense in which natural selection has shaped the structures and building materials of nests. Dawkins (1982) argued that various aspects of nest construction may be best understood as extended phenotypic effects. Dawkins suggested that, whereas the forces of natural selection directly act on the physical characteristics of a given nest, the downstream consequence is that those genes responsible for more well-constructed nests become more abundant in the gene pool. Hansell (2007) extended Dawkins's argument, suggesting that by imposing selective pressures on populations of nest builders over time, natural selection is responsible for the wide variety in the materials used to build nests, as well as the differences in the architectural designs of nests among closely related avian species. Those individuals that build stronger nests, nests better at insulating eggs and chicks, or nests that better protect against predation will have more surviving offspring. In this sense, natural selection acts on both the physical composition of different nests and the behavior responsible for nest construction. Zebra finches may even use information about past breeding success to inform subsequent decisions about nesting materials (Camacho-Alpizar et al. 2021), and a separate study of zebra finches found

that experimental manipulation of early-life exposure to different colored nesting material influenced the materials preferred by adolescents during the construction of their first nest (Breen et al. 2020).

Sexual selection may also play a role in nest construction for some species. Male weaver birds build nests that will eventually hold eggs without the assistance of the female, and in fact, male weavers construct these nests before they are even chosen as a mating partner. It seems that male weavers construct their nests, at least in part, to display their quality as a mate. Indeed, one study of baya weavers observed that the number of female visits to an incomplete nest predicted whether that nest would eventually be completed (Quader 2005). The same study also observed that females were more likely to choose nests that were built higher up, connected to thinner branches, and that were more neatly woven. The results of this study provide evidence that, at least for this species of weaver, nest construction is subjected to sexual selection, with better nest builders being more likely to attract a mate.

Nest building also occurs in many non-avian species, including several primate species. One study of nesting behaviors in chimpanzees (*Pan troglodytes*) found that chimpanzees preferred to nest above 1000 m, under dense canopies, and in relatively less humid areas (Koops et al. 2012). A study of nesting materials in western lowland gorillas reported a preference for specific species of plant, with individuals using an average of 4.9 different species per nest, but no seasonal shifts in preferences for different materials (Willie et al. 2014). Similar to avian species, nest-building primates also show preferences for certain nest characteristics, including both material and location, suggesting that in both aves and primates, selective pressures have likely shaped nest building behaviors.

Despite the large degree of variation in species that construct them, nests almost universally appear to serve a similar purpose: holding and protecting eggs and offspring. And although nests serve similar purposes, there is

considerable variation in the materials used to construct nests, and in the architectural designs of the nests.

## Nesting of Sea Turtles

Mohd Uzair Rusli

Universiti Malaysia Terengganu, Kuala  
Terengganu, Terengganu, Malaysia

## Nesting Behavior

Female sea turtles have a unique characteristic of returning to the same beaches on which they were born in order to nest (Brothers and Lohmann 2018). Upon leaving the nest early in life (after about 2 months in-nest incubation), sea turtle hatchlings will swim vigorously to escape predator-rich shallow waters and will never return until they reach sexual maturity about 20 years later.

Sea turtles are generally solitary, and in most species, individual female turtles nest on their own. However, out of the seven species of sea turtles worldwide, two species – the olive ridley (*Lepidochelys olivacea*) and Kemp's sea turtle (*Lepidochelys kempii*) – exhibit mass nesting, called *arribada*, the Spanish word for “arrivals.”

Nesting activity typically happens on sandy beaches with sediment types ranging from fine to coarse sands (Kelly et al. 2017). Most of the time, the nest is constructed above the high tide waterline to secure the incubating eggs for the approximately 2 month-long (range, 45–70 days) incubation period. The incubation process depends on temperature where the higher incubation temperature will shorten the time to hatching (Booth and Astill 2001; Jong et al. 2009). However, incubation temperature above 33–35 °C of sea turtle eggs might be causing low-quality and impaired locomotion of hatchlings produced to escape from their nests (Segura and Cajade 2010). Therefore, the behavior

of sea turtles constructed their nest under shaded or open area will result in variation in phenotype and performance of an individual.

## Nesting Period

Sea turtles are known as a highly reproductive species as one female can produce several clutches within a nesting season (Miller 1997). However, nesting activity seldom occurs annually. Typically, the interval between nesting seasons is between 2 and 4 years (Broderick et al. 2001; Chaloupka 2001; Chan 2010; Sims et al. 2008). Some scholars believe that this interval period occurs because sea turtles spend so much time in the open ocean, foraging and migrating from one feeding ground to another.

Within any particular nesting season, a female turtle will remain within the vicinity of a nesting beach and spend several months there in order to deposit multiple clutches. A single female may nest up to six times with interval of 10–14 days before the next nesting activity (Hart et al. 2010). The nesting period for a typical female lasts about 3 months before she heads back out to the sea.

Nesting activity typically occurs at night as sea turtles are very sensitive to disturbance from light and potential predators. Night nesting also helps turtles avoid dehydration from the long arduous crawl from the water to the beach and back again. The complete process may take between 2 and 4 h depending on the species and beach characteristics. Occasionally females also crawl out from the water but do not nest. This phenomenon is known as a “false crawl” (Talbert et al. 1980).

Sea turtles are likely to nest during high tide, probably to reduce the crawling distance from shoreline to the nesting spot. Due to the high drag of her heavy body weight (60–600 kg depends on species), nesting is energetically costly and seems exhausting to human observers. Teardrops can often be seen during the nesting process as a mechanism to excrete excess salt in blood (Lutz 1997).

## Nest Construction

Nesting activity starts when a mature female emerges from the water and crawls up to her nesting spot. When the appropriate spot is reached above the high tide level, a turtle will move both left and right flippers synchronously back and forth and start lowering her body until it reaches the same level of beach surface. This sand throwing behavior, termed “body pitting” may later help rear-flippers to reach deeper level. Hence, the depth of nest chambers is dependent on the size of a female’s rear-flippers.

When the turtle has stopped using its front-flippers, she begins to use her rear-flippers, which act like shovels to scoop the sand out of the nest cavity. This is known as “egg chambering.” During this activity, the turtle moves the rear-flippers alternately between left and right. The turtle is typically seen trying to maximize the depth of nest chamber by lifting up her body with the support from her front-flippers. The nest chamber is constructed in a shape similar to a flask, which is thought to equalize temperatures among all of the incubating eggs. Depending on the species, the nest chambers typically highly related to maternal morphology and the reproductive output (Bjorndal and Carr 1989).

Sea turtles often abort the nesting process if they found any hard surface such as roots, dead coral, or gravel while chambering. She may then move to another spot and start with body pitting again as described above or may return back to the water immediately, likely returning to the same beach the next night.

Once the nest chamber construction is completed, turtle lays eggs through ovipositor by dropping two to three at a time until there are about a hundred eggs per clutch. It is believed that when the eggs touch the tail of the turtle, this serves as a cue that the nest chamber is full enough. However, Hailman and Elowson (1992) suggested that this tactile feedback is not the only cue for termination of eggs laying as some of turtle had stop earlier. The whole process takes around 10 min, depending on the species.

Upon completion of egg deposition, a turtle will conceal the nest cavity with her rear-flippers. Then, the turtle will rest for about 5 min. During this short window, conservation workers can safely measure morphological characteristics and attach identification tags, before the turtle starts using both front flippers to continue covering the nest. While dispersing the sand over the covered egg chamber by using their front flippers, turtles moved gradually a few meters forward. This camouflaging behavior created an elongated mound of sand on the origin nest chamber hence will confuse potential predators (this is typically known as creating a “false nest”). When the nest is covered, the turtle will crawl immediately back to the sea.

## Introduction

The way in which an individual acts in response to a stimulus or situation is called “behavior.” Behavior is chiefly controlled by the central nervous system (i.e., brain and spinal cord). Behavior can be innate (present since birth) or is learned during a lifetime. Further it can be simple or complex. The simplest forms of the behavior are the “reflexes” which are innate in nature. For a reflexive behavior, the individuals may fail to perceive a conscious appraisal, as it primarily gets executed from the motor centers in the brain stem or spinal cord. Complex behavior, a varying motor action or response adjusted to the need of a situation, involves more than one component of the brain and is intricately regulated. A stimulus which is received at the sensory receptors is carried by the nerves to the sensory cortex which generates perception and further sends it to the cognitive and the effectors domains of the brain

where complex neural processing constructs a behavior from the substrate, in response. The comprehensive cortical processing of sensory feedback is essential for the conscious appraisal of a complex behavior. Reflex behavior is common to all the organisms, while complex behaviors are unique to the animal kingdom and denote their intellectual ability and hierarchy in the living system.

Complex behaviors can be innate or learned. Innate behaviors (as feeding or sexual behavior) are genetically determined. Innate behaviors involve hypothalamus and other subcortical centers and are associated with limited cortical processing in comparison with the learned behaviors. Emotional behaviors, which are largely innate, are regulated by limbic system which presents a unique set of cortical and subcortical centers. Learned behaviors may be driven by reward – a phenomenon called conditioning – or may not involve any reward at all, called nonassociative learning. A reward pathway which connects aminergic nuclei of the brain stem to the specific nuclei group in the forebrain has been considered as the driver of any reward-based behavior (Kiernan et al. 2014). Aminergic nuclei in the brain stem are known as the prime determinants of the adaptive behavior – which is largely a learned behavior helping the individuals in adapting to the environmental challenges.

How brain generates behavior has been an all-time curiosity of the human which has now developed into a distinct stream of the neuroscience, called *neuroethology*. In recent years, knowledge of the neural control of the behavior has got extensive research updates revolutionizing the existing understanding of the neuroethology. Behavioral roles have been found for many new brain regions which were earlier either not or little known. Recent research suggests extensive role of *anterior cingulate cortex* in decision-making. Basal nuclei and cerebellum have been found to bear important roles in behavior, in contrast to their earlier known roles which limited to the movement control. There are also updates regarding the role of the *insula* (a cortical island) and *claustrum* (a strip of gray matter), for which any cognitive/behavioral functions were earlier little

known. Uniquely, *habenula* – a subcortical set of nuclei which connects with brain stem – has been noted crucial in regulating adaptive behavior (Kumar et al. 2017b). Other than the central nervous system, two other nervous system types, i.e., “autonomic” and “enteric,” are also known to bear important roles in complex behavior. The current research adds extensively into their behavioral functions.

Present chapter takes a comprehensive look on the role of the three nervous system types involved in regulation of the animal behavior, and behavior-specific neural circuitries comprised of them, with a focus in human.

## Methods for Study of Neural Regulation of Behavior

Animal behavior is either studied by direct observations of its response to a given stimulus in a natural setting or through modeling of a behavior in laboratory settings. In laboratory settings, interventions like creating a lesion or inserting an implant, or the introduction of a pharmacological agent into the nervous system of an animal, can be done to model a behavior. These models can be further assessed by the standard neuropsychological tests.

For long, creating a lesion in the brain to know its impact remained a primary method to study a behavior. Implying the electrodes in targeted brain parts to record the local field potential (LFP – an electrophysiological signal created by summed up electric current arising from large population of neurons from the recording site) in the behaviorally activated neurons or to observe effect of an electrical stimulation, or pharmacological interventions, had been the next prevailed methods to study animal behavior in laboratory settings. These methods when combined with the neuroimaging modalities have brought revolution in the understanding of neural control of behavior.

There have been significant advances in neuroimaging (and recording) methods in recent years which have made structure-function coupling for the brain parts possible. Multimodal neuroimaging and data integration from chosen

combinations of the magnetic resonance imaging (MRI), positron emission tomography (PET), single-photon emission computed tomography (SPECT), near-infrared spectroscopy (NIRS), magnetoencephalography (MEG), electroencephalography (EEG), diffuse optical tomography (DOT), etc. have given edge to the behavioral research. The advances have given rise to a new stream of behavioral study, neuroeconomics – an interdisciplinary field which seeks to explain how decisions are made in the brain (Xue et al. 2010).

Structural magnetic resonance imaging (sMRI) has now got resolution of 7 and 9 tesla which is able to provide the structural details of the brain parts in living closer to that histological study in postmortem brain tissue. Use of contrast-based sMRI (mainly iron oxide) can detect the activity of targeted molecules with high sensitivity and specificity.

*Diffusion tensor imaging (DTI)* has revolutionized the knowledge on the fiber connections of the brain parts. DTI is a sub-modality of the structural MRI that encodes diffusion effects of the water molecules in the nuclear magnetic resonance signal by using bipolar magnetic field gradient pulses. The fiber tracts can be delineated in vivo based on the fractional anisotropy. *Constrained spherical deconvolution (CSD)* tractography is a modification of DTI which can provide better three-dimensional model of the neural tracts due to its ability to detect crossing fibers in the tracts.

*Functional magnetic resonance imaging (fMRI)* can depict brain activity by detecting the associated changes in brain hemodynamics by using blood-oxygen-level-dependent (BOLD) contrast. BOLD reflects cerebral blood flow (CBF) as brain function requires blood flow to supply oxygen for energy consumption by neurons. Event-related fMRI can also be used to label specific molecules with contrast agents called molecular MRI. A statistical method called *multi-voxel pattern analysis (MVPA)* implies feeding of fMRI data into a computer algorithm that automatically learns the neural patterns associated with specific thoughts or experiences.

*Single-photon emission computed tomography (SPECT)* is a functional nuclear imaging method often used to image awake behaving animals

(where a targeted brain part is stimulated using invasive electrodes or some other physical means). It uses an intravenous radiotracer to detect cerebral perfusion during activity and in turn neuronal activity (which depends on cerebral perfusion rate).

*Positron emission tomography (PET)* is the best to study neurotransmitter/receptor interactions. It has lower spatiotemporal resolution when compared to MRI. It is exquisitely sensitive for detecting the targeted molecules or processes.

*EEG* and *MEG* detect synchronized activity of an assembly of neurons by measuring LFP or magnetic fluxes. EEG and MEG can be used to explore brain cortical activation pattern with ultra-high temporal resolution and real-time recording of the event-evoked neural information flow. *Stereoelectroencephalography (SEEG)* uses *in-depth* electrodes (surgically implanted in the brain tissue) for recording electroencephalographic signals from desired subcortical nuclei in animal models.

Electrical recording of the cortex and *in-depth* brain parts has progressed much in recent years. Scalp electrodes have become more efficient. For intracranial recording, miniature multiplex electrode panels or multielectrode arrays (MEAs) can get surface recordings from large parts of the cortex very easily, and new hair-thin electrodes can reach *in-depth* brain parts without causing any significant brain damage. Wireless electrodes can be implanted in brain parts in behaving animals which can be operated from remote control to provide stimulation or recording. Magnetic transcranial and deep brain stimulation are now being frequently used to stimulate desired brain parts. Whole cell patch clamp (which can detect ionic currents in single neurons) can be used to detect neuronal activity at the level of single neurons in awake or behaving animals. Whole brain imaging of neuronal activity using fluorescent calcium indicators and multiphoton laser scanning microscopes in head-fixed behaving animals is a recent method for detecting behavior-specific neuronal circuitry.

*Diffuse optical tomography (DOT)* is an optical spectroscopy method which uses infrared

light to probe activity inside any organ. Light entering in the tissue can undergo multiple scattering, and as a result some photons are redirected back toward the tissue surface each time. The distance this light travels and the changes in its physical properties in that course carry information which can be decoded to measure events and map their locations within the brain tissue. Regional variations in oxy- and deoxy-hemoglobin concentrations as well as blood flow and oxygen consumption can be imaged by monitoring spatiotemporal variations in the absorption spectra of used light. DOT can be used to monitor brain activity; it can directly measure hemodynamic, metabolic, and neuronal responses to neurons and tissue and organ activations.

### Newer Methods

Use of inducible gene constructs for the membrane ion channels in model animals can provide high-quality information for the neural circuitry – behavior relationship. *Chemogenetics* uses systematically administered *Designer Receptors Exclusively Activated by Designer Drugs (DREADD)* targeted to the specific molecules (Kumar et al. 2018c). *Optogenetics* uses laser lights of specific wavelengths to control activation of ion channels in neurons that are genetically tagged with fluorescent biomolecules. Fine optical electrodes are inserted in the brain for light-induced manipulation of electrical activity in *in-depth* neurons and neuronal circuits. This method has revolutionized the study of animal behavior (Deisseroth 2010; Kumar et al. 2018a). *Sonogenetics* uses low-pressure ultrasound waves to activate the artificially ultrasonically sensitized neurons (Ibsen et al. 2015). *Brain-computer interface (BCI)* integrated with the neuro-recording methods like EEG is being used as a mode of study or manipulating a specific behavior based on the neurofeedback (Grau et al. 2014; Kumar et al. 2018a).

*Computational modeling (CM)* is a recent entry into the study of animal behavior. It uses computers to simulate and study the behavior of complex systems applying principles of mathematics, physics, and computer science.

The benefit of using this method is that it can predict the influence of numerous variables which characterize any system, in minuscule time, with minimum of efforts by creating simulation of the system (Pareek 2017). A simulation is created by manipulating the variables individually or in combination and observing how the alterations influence the outcomes – called in silico experiment. Computational models have the ability to study a system at multiple levels – known as multiscale modeling (Cipresso 2015).

CM is a unique tool to understand how individuals or groups influence each other's behavior in a social structure. *Virtual reality (VR)*-based experimental settings are used to manipulate behavior in a single or a small group of individuals, and information-based parameters are extracted to develop a basic computational model of the behavior dynamics. (*VR is a computer-generated simulation of the reality.*) These basic models are further used to develop simulations to understand and explain behavior dynamics at the social level in the context of the possible scenarios. CM can also be used to study behavioral pathologies in individuals or groups (Cipresso 2015).

### Neurodevelopmental Basis of Behavior

The earliest forms of behaviors in a growing fetus are simple sensorimotor reflexes when brain parts and neuronal tracts are still maturing. The primitive reflexes disappear after birth. Any return of the primitive reflexes in an adult is considered as the indicator of a neuronal lesion. Childhood and adolescent ages are the critical periods when an individual forms concepts about the environment surrounding it and develops “theory of mind, an ability to understand mental status of others,” which are very quintessential for learning social behaviors. As cognitive and behavioral domains are still maturing, children and adolescents are vulnerable to develop behavioral disorders. Poor rearing up conditions during childhood and adolescence are known to adversely affect social behavior of the individual. Certain individuals are considered more susceptible to develop such behavioral disorders due to their unique genotypic structure.

## Common Neural Mechanisms in Complex Behaviors

### Perception-Cognition-Action Triad

A behavior generates from the hierarchically arranged cortico-brain stem/spinal networks (top-down and bottom-up) of the central nervous system (CNS). Perception and cognition are the neural substrates for any behavior. Any given stimulus is received by a peripheral sensory organ which is further carried to sensory cortex of the brain through sensory pathways (entering either through the spinal cord or brain stem at the lowest hierarchical level and then through the midbrain and the diencephalon). In the sensory cortex, perception for the stimulus is generated (which can be further unified in a multimodal cortical area with the corroboratory perceptions from other sensory modalities). The perception is further encoded by cognitive domains of the brain in the form of a memory or learning, following which effectors domains generate a suitable response for the encountered stimulus based on the merits.

### Prediction Signaling, Error, and Response

It is a basic property of any neuronal ensemble that it would generate a prediction estimate against any incoming sensation or a motor command. This prediction (or *prediction signaling*) is further matched with the actual input to the nuclei. Any difference of the actual and expectant value is called *prediction error* which is used to correct the future predictions. Neuronal ensembles calculate saliency (strength) and valence (positive or negative character, which is important in reward predictions) of a stimulus. Any behavioral response is based on the prediction error values (den Ouden et al. 2012). Any behavioral response against a novel stimulus generates learning which can be stored in the specific parts of the brain as the memory patterns (or engrams), which will provide an experienced-based contribution to the future behaviors when a similar stimulus is encountered. A prediction error-based construction of the behavior will be further discussed in the section “*Behavior-Specific Neural Correlates*” of this entry.

### **Behavior-Induced Brain Plasticity and Vice Versa**

Behavior induces plastic changes in the brain components. The plasticity may involve brain part (like size of amygdala may increase in the anxiety disorders), connections, dendritic arborization and spine density, axonal sprouting, synaptic organization and formation, and neurogenesis (in hippocampus). Vice versa, the brain plasticity may have influence on cognitive abilities and behavior of the individual which in turn may induce further plasticity – a phenomenon known as meta-plasticity (Altenmüller and Furuya 2016) – and is regarded crucial for the behavioral modifications and learning motor skills.

### **Role of Neurotransmitters, Neuromodulators, and Neurohormones**

Neurotransmitters are the chemical messengers which facilitate communication of impulses at synapses. Neuromodulators (catecholamines derivatives such as dopamine, serotonin, noradrenaline, and many small peptides like enkephalin, endorphin, dynorphin, etc.) and neurohormones (which are secreted by neurons, like estrogen, oxytocin, and vasopressin) have the capacity to modulate transmission at the synapses. Though a behavior is not directly created at the synapses, synaptic communications create neural substrate for it. Along with the neurotransmitters, neuromodulators and neurohormones have critical roles in setting and maintenance of the mood. An intricately regulated cocktail of these neurochemicals not only determines the quality of synaptic communication but also sets the rate, rhythm, coupling, and synchronization of the oscillatory waves arising from cortical neurons – which is crucial for the construction of an appropriate response to the encountered stimulus (Kumar et al. 2018b).

### **Neural Basis of Sexually Dimorphic Behaviors**

We can distinguish the behavioral differences between male and female by looking at their varying responses to the same environmental stimuli, but neuroscientific basis of this is not very clear yet. The new research has gradually disapproved the earlier belief that some brain parts are sexually dimorphic. Accumulating evidence suggests the

sex-specific differences are not in the gross brain structures or neural connections but lie at the ultrastructural levels like transcriptomic and proteomic configuration of the specific brain parts and molecular arrangement and signaling at the neuronal synapses (Chen et al. 2019).

## **Salient Brain Parts/Nervous System Components and their Affiliated Behaviors**

### **Cerebral Cortex: Supreme Controller of Animal Behavior**

Ordinarily, the cerebral cortex is believed to have control over cranial and spinal regulation of motor actions. It also has limited control over basic/instinctive behaviors as hunger, thirst, or sex, which primarily involve hypothalamus. Brain has primarily four cortical lobes (frontal, parietal, temporal, and occipital lobes) controlling all kinds of behavior. Two minor lobes – insular and limbic – are also described which involve parts of the four primary lobes. (A detailed description on behavioral role of insular cortex has been provided later in this entry in segment “Emerging behavioral role for other brain parts and nervous system components.” Limbic cortex is further described with limbic system in section “[Emotional Behavior](#)” under section “[Behavior-Specific Neural Correlates](#).”) Prefrontal cortex (PFC) (anterior part of the frontal lobe) is the most important cortical part involved in the control of executive, social, emotional, or instinctive behaviors. Distinctive parts of the prefrontal cortex are involved in specific aspects of the behavior, e.g., dorsolateral prefrontal cortex (DLPFC) is involved in executive behaviors (showing intelligence) like planning, thinking, making judgments, and problem-solving. Ventrolateral and ventromedial/orbital (VLPFC and VMPFC or OFC) parts concern more to the control of social and emotional components of a behavior. Anterior cingulate cortex (ACC) is said to have crucial role in decision-making and personal/social conflict resolution. VLFC, VMFC/OFC, and ACC are also involved in fetching attention of the individual to a salient stimulus, hence working as a self-referencing center.

### Cortical Modularity-Based Cerebral Mechanisms

Cortical domains in the brain are arranged into large-scale structural and functional networks. A large-scale network can be decomposed into sets of densely connected small-world networks (based on the short average distances or closeness between connecting elements) and activated during a specific cognitive function or sensory perception (Meunier et al. 2010). Major cognitive cortical modules are saliency network (SN), default mode network (DMN), dorsal attention network (DAN) and ventral attention network (VAN), task-positive network (TPN), and central executive network (CEN). Each such small-world cortical network is defined as a module – which can be represented on a graph and contains dense structural/functional connections (called edges) between its components (called nodes). A cortical module is an evolutionarily conserved and functionally segregated network. There could be further levels of hierarchy within a module, where it can be decomposed into more densely connected clusters or subsets (Meunier et al. 2010). These cortical modules are delineated by the graph-theoretic study of fMRI connectivity pattern during rest- and task-related activity. DMN and executive/attention networks exist in anticorrelation (activation of one has deactivating influence on another) relationship and deal with “task-negative” and “task-positive” cognition, respectively. DMN gets activated when an individual is at rest, absorbed into autobiographical moments, or self-monitoring detached from the external world. Conversely, executive/attention networks get activated when individual follows a task or engages to the external world. The DMN grossly includes VMPFC, bilateral posterior cingulate cortex (PCC) and retrosplenial cortex (RspC), inferior parietal lobule (IPL), parts of the hippocampal formation, medial temporal lobes (MTL), and the angular gyrus. The CEN is anchored in DLPFC and PPC. The DAN is organized bilaterally and grossly comprises the intraparietal sulcus (IPS) and the frontal eye fields (FEF) of each hemisphere. The VAN which is said to be lateralized to the right hemisphere involves temporoparietal junction (TPJ) and the ventral

frontal cortex (VFC). Salient network (SN) comprises anterior insula (AI) and dorsal anterior cingulate cortex (dACC). SN detects relevant internal or external stimuli and also acts as a switch between DMN and ACN (and DAN/VAN).

Other than above described major cortical modules, there are many minor modules, like that for face, object, color identification, or memory recall. Major sensory perception cortical modules are that for visual, olfactory, tactile, and auditory perception.

Cortical modules hold key to specific neurophysiological processes or sensory perceptions, and cognitive functions (Hilger et al. 2017), and are building blocks for any behavior. Several of the cortical modules can be recruited to orchestrate behavioral response to any stimulus.

### Theory of Mind: A Basic Cortical Function in Social Behavior

Theory of mind is defined as a cognitive ability to understand mental status of others and develops during childhood and adolescence (as we described above). This ability is more evident in human, primates, and other animals showing higher engagement in social behavior. This is an essential ability for peaceful coexistence in a society which depends on strong social relationships and cooperations with each other. Neural correlates of *theory of mind* are not much understood though mainly cortical parts (prefrontal cortex, insular cortex, parts of parietal and temporal cortices (inferior parietal lobule, temporoparietal junction, posterior part of the superior temporal sulcus, etc.)) are said to contribute to this. A unique type of cortical neurons – “*mirror neurons* which activate when animals view others doing actions” (Carrillo et al. 2019) – is said to be crucial in developing this ability (has been described in detail along with “insula and mirror neurons” in section “[Emerging Behavioral Role for Other Brain Parts and Nervous System Components](#)”). Another type of neurons (similar to the *mirror neurons* in cortex) was recently reported in amygdala, called *simulation neurons*, which help in predicting and creating a mental simulation of others’ probable actions based on their observations (Grabenhorst et al. 2019) (further studies

will be necessary to develop a concrete concept in this regard).

### **Hypothalamus: Master Regulator of Innate Behavior**

Hypothalamus is also called as visceral brain due to its concern with the visceral functions like feeding, hunger, and thirst. It is also involved in the instinctual behavior like sex and reproduction. Hypothalamus is also the master regulator of endocrine organs, and it is the highest autonomic center in brain (Kumar et al. 2018c). Thus, hypothalamus presents a hub connecting the endocrine regulatory axis and autonomic nervous system to the rest of the brain.

### **Hippocampus: A Memory Base for the Cognitive Flexibility and Social Behavior**

The role of hippocampus has been considered important in creating cognitive flexibility and social behavior (Rubin et al. 2014). Hippocampus exerts its influence on behavior through memory. In hippocampus, registration and *long-term potentiation (LTP)* of the memory occur (Kiernan et al. 2014). Memory contents create a neural substrate for any experience-based behavior. Hippocampus has an exclusive role in learning which can create new experiences which in turn can amend an old behavior. Nearby parahippocampal region (entorhinal cortex) is known to register spatiotemporal details of the surroundings the animal resides in that creates important attribute to a learned behavior. Hippocampus has also an influence on the *hypothalamo-pituitary-adrenal (HPA) axis*, through which it regulates endocrine homeostasis, which in turn can influence behavior.

**Hippocampus Microanatomy (In Brief):** The hippocampus is located in the medial temporal lobe. It contains two parts: the hippocampus proper and the dentate gyrus. The hippocampus and dentate gyrus (DG) have the shape of a curved tube, which can be compared to a seahorse and a ram's horn (Cornu Ammonis – CA). Hippocampal subfields CA1, CA2, and CA3 are named by abbreviation of Cornu Ammonis. Hippocampus proper and DG present an allocortex bearing only three layers. The major neurons in the

hippocampus proper and DG are pyramidal neurons and granule cells, respectively. The hippocampus is reciprocally connected to various cortical and subcortical structures. Its prime cortical connection is from the entorhinal cortex (EC). The EC is located in the parahippocampal gyrus, a cortical region adjacent to the hippocampus bearing all six layers. The cortical transition zone (from three layers to six layers) between the hippocampus and EC is called subiculum. The entorhinal cortex (EC) is strongly and reciprocally connected with many cortical and subcortical structures as well as with the brain stem. Its major efferents to the hippocampus enter via perforant pathway bypassing the subiculum (Kiernan et al. 2014). Figure 1 provides a schematic description of the chief hippocampal microcircuitry connecting to EC. The reentrant signals through hippocampal-EC loop are associated with registration and long-term potentiation of the new memories.

### **Basal Nuclei: A Tool for Selection of Appropriate Behavior**

Basal nuclei (BN, earlier known as basal ganglia) are a set of subcortical gray matter collections located in vicinity of the diencephalon (Kiernan et al. 2014). Earlier known roles of basal nuclei in behavior were limited to the motor functions like movement, but new research establishes its essential role in reward value-guided or motivated behavior – it helps to decide which choice will be more rewarding to follow (Hikosaka et al. 2014). Reward can be evaluated here for the short-term and long-term benefits – which give individual chance to switch from a choice based on its current value (Kim and Hikosaka 2015). Simply put, basal nuclei help to select most appropriate behavior among the available alternatives in response of an external or internal stimulus. The appropriateness of a choice is decided by competitive actions between three pathways in the basal nuclei neural circuitry, namely, direct, indirect, and hyperdirect pathways (Nambu 2009).

### **Basal Nuclei: Basic Anatomy (In Brief)**

The main components of the basal nuclei – as defined functionally – are the striatum (dorsal

**Neural Control of Behavior, Fig. 1 Hippocampal microcircuitry in behavior** (Sensory signals drive the perforant path (PP, black) excitatory inputs from EC II and III layer pyramidal neurons to granule cells in the dentate gyrus (DG, black), which in turn sends mossy fiber axons (black) to CA3, and then CA3 feeds excitatory inputs onto CA1 neurons through Schaffer collaterals (SC,

black). A major output of the hippocampus arises from CA1 pyramidal neurons, which projects back to EC (V and VI layers) thus completing the hippocampal-EC loop. Hippocampal microcircuitry also contains GABAergic interneurons (red) which modulate pyramidal neuron activity in a domain-specific manner)

striatum comprising of caudate nucleus and putamen and ventral striatum comprising of nucleus accumbens and olfactory tubercle), globus pallidus, substantia nigra, and subthalamic nucleus (STN). The globus pallidus is functionally divided into external (GPe) and internal (GPi) domains. The substantia nigra which is actually a part of the midbrain is functionally divided into two parts: the inner pars compacta (SNc) and the outer pars reticularis (SNr). The basal nuclei present a three-tier structure (input, caudate nucleus and putamen; intrinsic, GPe, STN, SNc; and output GPi, SNr nuclei) connecting cerebral cortex in a cortico-basal nuclei-thalamo-cortical (CBnTC) loop.

Basal nuclei microcircuitry in behavior is organized in CBnTC loops. There are four types of CBnTC loops which can be recruited for any behavior (Table 1) (Kiernan et al. 2014).

The three known basal nuclei pathways (direct, indirect, and hyperdirect) involve one of these CBnTC loops. Figure 2 presents a schematic diagram of the basal nuclei microcircuitry implied in behavior.

### Cerebellum: A Prime Moderator for all Behavioral Actions

Like the basal nuclei, the cerebellum was primarily known for its role in movement. New evidence suggests the cerebellum is involved in moderation of each of the functions of the cerebrum; hence supposedly it has a function to modulate the cerebral control of cognition and behavior. It was reported to be involved in the control of the reward-oriented behavior mediated by its projection to VTA – a brain stem dopaminergic nuclei which also gets projections from the prefrontal cortex (Carta et al. 2019). It gets activated several milliseconds prior to the cerebrum when we are to initiate an action or even in showing imaginary of an action (Kiernan et al. 2014). It assembles and provides experience-based feedback for correction of the prediction error (made by executive and motor centers in cerebral cortex) which brings perfection to a learned behavior (Rapoport et al. 2000).

### Cerebellar Microanatomy (In Brief)

A histological section of cerebellum would show an outer folded cortex (gray matter) surrounding

**Neural Control of Behavior, Table 1** Cortico-basal nuclei-thalamo-cortical loops in behavior

Adapted from Bar’s The Human Nervous System: An Anatomical Viewpoint, Tenth Edition

an inner medulla (white matter) which contains deep nuclei embedded within it. There are three layers to the cerebellar cortex; from outer to inner, these are the molecular, Purkinje, and granular layers. The function of the cerebellar cortex is essentially to modulate information flowing through the deep nuclei embedded in the medulla. The molecular layer is outermost layer of the cerebellar cortex, containing two types of inhibitory interneurons: the stellate and basket cells. It also contains the dendritic arbors of Purkinje neurons and parallel fiber tracts (axons of granule cells), coming from the granular layer. The middle layer contains only one type of cell body – that of the large Purkinje cells. Purkinje cells are the primary integrative neurons of the cerebellar cortex and provide its sole output which is inhibitory in nature. The innermost layer contains the cell bodies of two types of cells: the numerous and smaller granule cells and the larger Golgi cells (Kiernan et al. 2014). Figure 3 provides a schematic description of functional cerebellar microcircuitry implied in behavior.

**Reticular Formation (RF): Center for the Generation of Consciousness, Arousal, and Behavioral Reflexes**

RF is a diffuse neural network comprising of neuronal cell bodies and nerve fibers located in brain stem core. RF contains diverse set of nuclei arranged in columns which send axons up and down to almost all brain parts including cerebral cortex and cerebellum and spinal cord segments. Their dendrites create an entangled network locally, contact with the cranial nerve nuclei which are located in the brain stem, and receive collaterals from ascending and descending tracts passing through the brain stem (except that in the posterior column for fine touch, pressure, and proprioception) (Kiernan et al. 2014). Among RF nuclei also are the aminergic nuclei which secrete adrenaline/noradrenaline, dopamine serotonin, acetylcholine, etc. and take part in reward-oriented and adaptive behavior. Ascending cortical projections from RF, called reticular activating system (RAS), relay through nonspecific midline nuclei of thalamus and then spread diffusely to all over the cortex. RAS is said to provide arousal to

**Neural Control of Behavior, Fig. 2 Basal nuclei microcircuitry in behavior** (All the basal nuclei pathways begin with the cerebral cortex stimulating striatum by the glutamatergic efferents. Thereafter, striatum inhibits Globus pallidus “externa” in “In-Direct” and “interna” in “Direct” pathway by the GABAergic efferents. An inhibited Globus pallidus “interna” releases less amount of GABA to the adjacent Sub-thalamic nucleus, which is directly stimulated by the efferents from cerebral cortex in “Hyper-Direct” pathway. Subthalamic nucleus in turn stimulates the “interna” by more amount of glutamate

being released from it. Efferents from Globus pallidus “interna” now inhibit the thalamus, the extent of which depends upon the pathway being followed, more inhibition in In-Direct and Hyper-direct pathway as compared to that in Direct pathway. The thalamus by default stimulates the cortex by the glutamatergic efferents, which is more in Direct pathway (disinhibition) than the rest of the two pathways (inhibition). Depending upon the resultant stimulation of the motor cortex, appropriate behavior can ensue. The inhibition made by Hyper-Direct pathway is more than the In-Direct pathway)

the cortex hence to contribute to the alertness and attention. Secretions of aminergic nuclei which are mostly neuromodulators in function are also said to set the mood of the individuals. Owing to its reciprocal connections of RF to almost all brain parts similar to the claustrum, it is believed to be the “seat” of consciousness – from where the state of consciousness is controlled and maintained. Damage of RF creates coma-like conditions. RF also has reciprocal connections to autonomic centers like hypothalamus and in lateral horn of spinal segments, through which, it controls the ANS and the endocrine system. RF also has important role

in generation and maintenance of sleep, rhythmic control of respiration and cardiovascular functions, and maintenance of tone of the axial and limb muscles. Sleep is identified with reduced activity in RF neurons, in turn, less activation of the cortex through RAS. Sleep also helps to refill depleted store of aminergic neuromodulators. It has a modulatory role in pain as ascending spinothalamic fibers send collaterals to RF. Numerous nuclei of RF create polysynaptic circuits for certain reflex behaviors like chewing and eating, breathing, and head-neck movements in response of a visual or auditory stimulus.

**Neural Control of Behavior, Fig. 3 Cerebellar micro-circuitry in behavior** (The Climbing fibers and Mossy fibers are the two afferent fibers to the cerebellum. The Climbing fibers provide excitatory input from the inferior olivary nucleus of the medulla, on dendritic shafts of the Purkinje cells. The Mossy fibers are coming mainly from the cerebral cortex via pontine nuclei. The Mossy fibers synapse with the Granule cells in the granular layer of the cerebellar cortex, which in turn extend their axons into the molecular layer, where it divides and continues as the parallel fibers. The Purkinje cells are the only output of cerebellar cortex which project to the deep cerebellar nuclei. Since the Purkinje cells are GABAergic, the output of the cerebellar cortex is absolutely inhibitory. However, the deep cerebellar nuclei receive excitatory inputs from

the collaterals of the mossy and climbing fibers. The Purkinje cell inhibition of the deep nuclei serves to modulate the level of this excitation. This inhibitory activity of Purkinje cells is modulated by the interneurons like Basket cell (on the body) and stellate cell (on the dendritic shaft) from the molecular layer; both of the latter cells receive excitatory inputs from the parallel fibers. The molecular layer contains the apical dendrites of a cell type called Golgi cells; these neurons have their cell bodies in the granular cell layer. The Golgi cells receive excitatory inputs from the parallel fibers and in turn provide an inhibitory feedback to the granule cells. The output from the deep cerebellar nuclei reaches the thalamic nuclei and then to the motor cortex modulating their ongoing neuronal activity)

### Autonomic Nervous System (ANS): Prime Controller of Adaptive Behavior

Autonomic nervous system (ANS) is known to have very important role in innate as well as learned behavior. ANS has the sympathetic and parasympathetic components and bears a larger bodily spread than CNS. Hypothalamus presents the highest center of the ANS with vaguely distinguishable sympathetic and parasympathetic components. Brain stem contains the parasympathetic outflow only. Spinal cord contains thoracolumbar sympathetic outflow and sacral segment parasympathetic outflow. ANS is engaged in control of the animal behavior, by resetting hypothalamic circadian clock in

suprachiasmatic nuclei (SCN) and the neuroendocrine balance along the HPA axis, in turn, influencing neuroeffector communication at the peripheral targets in response of the external or internal stimulus. Hypothalamic autonomic nuclei send reciprocal connections to spinal autonomic centers. Innate behaviors like hunger, thirst, and sexual behavior are known to be regulated by contrasting influences of sympathetic and parasympathetic components of the ANS. Sympathetic component of the ANS is said to be greatly involved in the adaptive behaviors which present survival challenges like fight, flight, and fright situations (Kumar et al. 2018c). An activation of sympathetic component is associated with

aggression, anxiety, panic reaction, and disturbed appetite; in contrast an activation of parasympathetic component may be associated with ease of the mood, relaxation, good appetite, sexual excitation, and orgasm.

### **Emerging Behavioral Roles for Other Brain Parts and Nervous System Components**

#### **Insula and "Mirror Neurons": In Awareness of the Self-Action and That of Others**

Insular cortex which is anatomically buried between frontal, temporal, and parietal cortices is said to be involved in introspection and awareness of the "self-actions" (Namkung et al. 2017). A specific type of neurons, "mirror neurons," which are said to be present in anterior part of the insula (and also in frontal, temporal, and parietal cortices surrounding it), and ACC are believed to be principle to the awareness of the "self-actions" (Ramachandran 1995). Mirror neurons are also present in premotor regions of prefrontal cortex, temporoparietal junction (TPJ), or inferior parietal lobule (IPL). These neurons were first reported in macaque monkeys, when it was found that these neurons activated not only during performance of a task but also when a monkey was made to observe others doing it. Mirror neurons were also said to be behind social behaviors like understanding what others think or feel (hence in empathizing) (Carrillo et al. 2019), or learning by imitation of others' actions (Ramachandran 1995).

#### **Habenula: In Reward-Based Decisions and Adaptive Behavior**

Habenula is involved in the regulation of release of neurotransmitters and modulators from brain stem aminergic nuclei which is thought to be a central mechanism for developing an adaptive response to a persistent stimulus. Habenula is an evolutionarily conserved bilateral structure located at the interface of the diencephalon, basal nuclei, and brain stem which works as a gateway between cortical-subcortical and brain stem structures (Kiernan et al. 2014; Kumar et al. 2017b). It is thought to function as a switchboard for regulating emotional behavior in

conditions facing survival challenges (e.g., to avoid or approach or submission or freezing in response of a stimulus). Medial and lateral components of the habenular pathway are involved in positive and negative reward prediction, respectively, making their balanced action crucial for decision-making in reward-oriented behavior (Kumar et al. 2017b). Any adaptive behavior also involves modulation in the settings of the hypothalamo-pituitary-adrenal (HPA) axis.

#### **Clastrum: In Unified Perception and Consciousness**

Clastrum is a thin sheet of gray matter sandwiched between insular cortex and striatum (it is separated from the insular cortex by the extreme capsule and from the striatum by the external capsule). Its unique location allows it to connect to all parts of the cerebral hemisphere reciprocally. It also sends reciprocal connections to contralateral hemisphere and other brain parts as hippocampus, amygdala, basal nuclei, thalamus, brain stem, and nearly all other parts of the brain. Uniquely, contralateral claustrums also connect with each other through interclaustral fibers. Empirical studies are scarce on the functional role of claustrum. Any direct role in behavior is not known, but recently proposed functions to claustrum suggest that it creates a neural base for production of any behavior. A study in the epileptic patients which placed electrodes in at one site of the white matter tract beneath the claustrum made the patient to stare blankly ahead with no recall of event when stimulus was removed (Koubeissi et al. 2014). The above said observation suggested mechanistic role of claustrum in the generation of consciousness. Claustrum fibers topographically connect with the deeper layers of cortex (mostly layer six). Claustral efferents to the cortex mostly end at the interneurons hence indirectly bear inhibitory influence on the pyramidal neurons. Inhibition of the cortex by the claustrrocortical fibers is said to have modulatory effect on the electrical activation pattern of the cortical segments (Jackson et al. 2018). Studies also suggested its role in real-time synchronization of electric waves and oscillatory coupling of two cortical regions bound to a common

cognitive function (Narikiyo et al. 2018). Francis Crick, based on its universal cortical connections (and also to the other brain parts) and role in coordination of the cortical electrical activity, proposed its role in generation of consciousness and being conductor of the information flow through the cerebrum (like conductor of an orchestra who directs whole band!) (Crick and Koch 2005). Function of claustrum resembles to an electrical device which performs multimodal integration of the stimulus information across the brain parts hence helps to create a unified sense of perception and generates a continuous flow of consciousness.

#### Enteric Nervous System (ENS): Mediator of the Gut-Motivated Behavior

ENS-CNS connection has given rise to concept of gut-brain axis. ENS is predominantly autonomic in function, and in concert with the gut hormones, it helps to maintain mood and emotion of the individual. New research has established its role in reward-mediated behavior. Uniquely, enteroendocrine cells in the gut mucosa were found to connect to the vagus nerve which is a parasympathetic nerve supplying the gut (Han et al. 2018). Right vagus nerve which innervates gut was found to carry gut impulses to the dopaminergic nuclei in the brain stem – which present important component of reward pathway connecting to the forebrain (Han et al. 2018). Parkinson's disease, a neurodegenerative disease of nigrostriatal pathway in the brain, is believed to start in ENS neurons of the large gut. A dysregulation of gut-brain axis has also been found implicated in the psychological stress and mood disorders like anxiety and depression.

## Behavior-Specific Neural Correlates

### Simple Behavior

#### Limb Reflex

A reflex is a rapid and involuntary response to a stimulus or cue. It is controlled at the level of spinal cord and is considered as a protective mechanism to a suddenly presented threatening stimulus (which is either painful and/or can

potentially injure the organism). A reflex is generated by a sensory-motor circuit of spinal neurons (Fig. 4) and doesn't involve a cortical control. Certain of the reflexes are also controlled at the level of brain stem; these are head and neck movements, mastication, and vital bodily functions such as cardiovascular circulation and respiration.

### Complex Behavior

#### Emotional Behavior

Emotional behavior is said to be generated and controlled by the *limbic system* in the brain. *Limbic system* comprises a rim of cortical mass surrounding the diencephalon – also called as *limbic lobe*, a set of subcortical nuclei – and white matter connections between them (Fig. 5) (Kiernan et al. 2014). *Amygdala*, a quasi-cortical gray matter mass, is one of the main components of this system. Amygdala is also called a center for fear, aggression, anxiety, and panic, or more correctly, it predicts salience value for any emotional information (Janak and Tye 2015). A connection between amygdala and prefrontal cortex is said to exert control over impulsive behavior where prefrontal control is inhibitory to amygdala, and their relationship is antagonistic (Volman et al. 2011).

The neural circuitries related to memory, centered at hippocampus, are extensively connected to the limbic system (as memory contents make essential ingredients of any emotional behavior). Also, autonomic and endocrine systems, which are centered at hypothalamus, are intensively linked with the limbic system, and their associated activations contribute to the physical and psychological manifestations of any emotional behavior.

#### Reward-Driven Behavior

*Mesolimbic or reward pathway* – a dopaminergic circuitry – connects *ventral tegmental area (VTA)* in the midbrain to ventral striatum or *nucleus accumbens (NAc)* in the forebrain (Kiernan et al. 2014). This is the prime circuitry (VTA-NAc) involved in all kinds of reward-based behavior including natural responses for food and sex and social interactions (Fig. 6).

**Neural Control of Behavior, Fig. 4** A limb reflex arc (Hammer tap stretches tendon which in turn stimulates sensory receptors (spindles) in the agonist muscles. Sensory neurons (blue) synapse with and excite motor neurons (brown) in the ventral horn of the spinal cord. The motor neurons innervate agonist muscle fibers (brown, intact

line), and their stimulation causes immediate contraction of these muscles. Sensory neurons also excite spinal interneurons (purple) which in turn synapse to and inhibit motor neurons innervating the antagonist muscles (brown, broken line), causing their relaxation)

**Neural Control of Behavior, Fig. 5** Limbic system (The limbic system is a complex set of structures found on the central underside of the cerebrum, comprising inner sections of the temporal lobes and the bottom of the frontal lobe. It combines higher mental functions and primitive

emotion into a single system often referred as the emotional nervous system. The primary structures within the limbic system include the amygdala, hippocampus, thalamus, hypothalamus, basal ganglia, and cingulate gyrus)

**Neural Control of Behavior, Fig. 6 Reward pathway**  
 (The reward pathway is principally a dopaminergic pathway (yellow, solid line) that connects ventral tegmental area in midbrain to nucleus accumbens of ventral striatum and the prefrontal cortex of cerebrum. Apart from dopaminergic efferents, the nucleus accumbens also receives

inputs from the Glutamatergic neurons (red, broken lines) of the hippocampus, amygdala, and medial prefrontal cortex. After being activated by glutamatergic inputs, GABA release (black, broken lines) occurs onto the ventral pallidum, consequently causing cortical disinhibition)

This pathway is intensely connected to various cortical and subcortical regions, hippocampus, and brain stem nuclei. Prefrontal cortex keeps this circuitry inhibited and hence puts a break on reward-based behavior. This circuitry is involved in the addictive behavior and is also implicated in obsessive-compulsive disorders. Reward pathway is evolutionarily conserved among animal species which is based on the release of dopamine when presented with a desirable stimulus. Same circuitry is involved in aversive behavior and stress where a reduction in dopamine release brings displeasure.

*Reward system* works on the prediction error signaling (den Ouden et al. 2012). Reward centers, which contain dopamine-releasing nuclei, generate prediction for the expected reward following behavior. A prediction error is computed by these nuclei deducting the prediction estimate from the actual reward value (den Ouden et al. 2012). When this actual reward is more than what was expected, a positive prediction error is

generated which causes release of dopamine – causing pleasure and in turn enforcing/motivating the individual to repeat the behavior. When actual reward is less than expected, a decrease in dopamine release (depression) is to occur – causing displeasure and in turn aversion from that behavior. When expectation is fulfilled, there has to be a normal release, causing no/or little enforcement to repeat the behavior. There is hierarchical difference in coding of reward along the reward pathway. The neurons at the down most center, SNc/VTA, activate with any novel information irrespective of its nature (i.e., each novel information is rewarding to the subject) based on its saliency. Neurons in NAc encode both saliency and valence of any incoming information. PFC encodes saliency as well as valence of any incoming information though its components exert differential influence on the reward pathway. Neurons in VMPFC/OFC activate more in positive prediction signaling, i.e., reinforce a rewarding behavior, and in DLPFC activate more in the

negative prediction signaling, i.e., create aversion for a non-rewarding behavior (Fouragnan et al. 2018).

### Adaptive Behavior

Adaptive behaviors, like response of the individual to a threatening or rewarding stimulus or situation like success or failure, win or defeat, have a complex neural circuitry which chiefly involves medial and orbital PFC, ACC, and anterior portion of the insula. Also are involved in this, cortical and subcortical components of the reward pathway, septal nuclei, and anterior hypothalamic nuclei. Emerging evidence suggests master role of the habenula in regulation of the adaptive behavior (has been described in detail in section “Emerging Behavioral Role for Other Brain Parts and Nervous System Components”).

**Miscellaneous: Love, Lust, Hate, Disgust, Religious/Ideological Fundamentalism, and Crowd Behavior** Though available knowledge on neural correlates of these behaviors is still limited, functional neuroimaging studies put some light on the brain parts grossly involved. Affectionate love is known to activate specific cortical and subcortical components of the limbic system which is overlapped but effectively distinct from the sexual attraction. The core brain regions that activate in a loving behavior are medial PFC, ACC, anterior insula, head of caudate nucleus or putamen, and VTA (Diamond and Dickenson 2012). In sexual attractions, activation of caudate nucleus and VTA is less distinctive, and an additional activation of the amygdala and hypothalamus occurs (Diamond and Dickenson 2012). Showing hateful and disgust behaviors also causes activation of the amygdala. Hateful behavior similar to the loving causes activation of the putamen and insula but, in contrast, causes deactivation of frontal, temporal, and parietal cortices (Zeki and Romaya 2008). Reward (or aversion) pathway is activated both in loving and hateful (or showing disgust) behavior. More ventral regions of the striatum and pallidum get involved in rewarding behavior like lust or aversive behaviors like hate or disgust. Increase in secretions of oxytocin by the hypothalamic nuclei (Heinrichs et al. 2009) and neurotrophins by

cortical neurons is known during loving behavior (Emanuele et al. 2006). Religious and ideological fanaticisms (fundamentalisms) are known to cause more activation of medial/ventral prefrontal cortex with relative silencing of DLPFC. DLPFC is thought to have role of a critic and activates more in a rational behavior – when individual uses reasoning to select a response (Harris et al. 2009). Crowd behaviors involve complex interactions between prefrontal cortex and limbic system components, with a lesser prefrontal cortex-mediated inhibition of the amygdala (Huis in ‘t and de Gelder 2015). An added influence of oxytocin and vasopressin (secreted by supraoptic and paraventricular nuclei of the hypothalamus, respectively) on decision-making by individual members has been evidenced in such behaviors (Heinrichs et al. 2009).

### Neural Basis of the Pathological Behaviors

Brain parts involve differentially in various known pathological behaviors. A dysregulation of reward pathway is associated with many pathological behaviors like addiction, substance abuse, and gambling (Yun et al. 2016). An amygdala-prefrontal imbalance has been associated with aggression, anxiety, depression, and panic reaction and the diseases like major depressive disorder (MDD) and bipolar disorder (BPD) (Volman et al. 2011). MDD and BPD have also been linked with altered activity of hippocampal neurons. An abnormal activity at temporoparietal cortical junction (TPJ) has been associated with hallucinations in schizophrenia. A hyperactivity of the dopaminergic neurons in reward pathway has been noted in psychotic disorders. A dysregulated brain plasticity also has been attributed for the pathological behavior, like excess anxiety, aggression, panic, or post-traumatic stress disorder (PTSD) (Kays et al. 2012). Social defeat and self-harming behaviors involve experience induced dysregulated plasticity in the brain regions involved in adaptive behavior like prefrontal cortex, amygdala, and aminergic nuclei in the brain stem. Dysregulation of the basal nuclei circuitry has been suggested in obsessive-compulsive disorders (OCDs).

Dysregulation of the neural circuitry involved in adaptive behavior also can give rise to certain behavioral pathologies. Repeated social defeat may induce a state of chronic unpredictable stress (CUS) and learned helplessness (a behavioral state in which individual no more explores for a safer option) in the individuals. CUS may be a reason for self-harming behavior seen in some individuals – which supposedly give them some sense of release from a conflicting condition or mental strain (Blasco-Fontecilla et al. 2016).

Owing to the increasing daily life use of new information technology facilitated digital devices like computers and smartphones, certain new behavioral disorders have emerged. “Problematic use of the Internet (PUI)” is an umbrella term for such disorders which involves “Internet video gaming and pornography,” excessive social media network use, and selfitis – an excessive preference for selfie taking and posting it on social media. Though many of the PUI-affiliated disorders are still not recognized by Diagnostic Statistical Manual (DSM) of psychiatry, emerging research suggests these behaviors involve reward system of the brain quite similar to other recognized addictive behaviors (Kumar et al. 2017a).

## Neural Impulse

Lenin D. Ochoa-de la Paz

Medicina, Universidad Nacional Autónoma de  
México, México City, Mexico

In the 1880s, Santiago Ramón y Cajal made a series of significant observations using a histological staining technique developed earlier by Italian physician Camilo Golgi (1843–1926). These discoveries were based on his ability to demonstrate the extensive, and oddly branched, individual elements of all nervous systems. These basic elements are the neurons, considered the basic unit of the nervous system (Nichols 2001).

Cajal's discoveries led to the establishment of the “neuron doctrine,” which states that the nervous system, like other organs, is made up of individual cells, in this case “neurons.” These neurons process and exchange signals with one another at specific points of contacts called synapses, called so by the neurophysiologist Charles Scott Sherrington (1857–1952). The idea of “reticular” organization, in which the cells of the nervous system were supposedly fused into a multicellular, syncytium-like continuum, therefore had to make way for the extension of cell theory to the nervous system. The discovery of the

nervous system are really system of the neurons, provide the first step for a number of observations and scientific investigation about the function of the brain, and marked the birth of the modern neurobiology (Sherrington 1906).

Nowadays, it is well known that the nervous system is composed of two main types of cells: neurons and glial cells. Glial cells (from the Greek word that means “glue”) outnumber neurons by about 10–1, and they account for about half of the volume of the nervous system. Together, glial cells nourish the neurons, remove their wastes, and defend against infections. Glial cells also provide a supporting framework for all nervous system tissue. Individual neurons are organized into tissues called nerves, which are grouped into nerve bundles and surrounded by protective connective tissue. Like optical fiber cables, which carry many individual wires from one part of network to another, the nerves extend the neurons throughout the entire central and peripheral nervous system (Nicholls 2001).

Just like glial cells, neurons must fulfill metabolic functions and participate in the exchange of substances; they have the same genes, the same biochemical mechanism, and the same organelles as other cells. However, neurons differ from other cells in one important thing, they process information and transmit it in the form of electrical impulses to neighboring cells. Each single neuron contributes to information processing in several ways. As receiver unit, it takes up signal from other neurons and converts these signals into propagated electrical activity to other location and then transfers the electrically encoded information to receiving neurons. The process of signal conversion and conduction is favored by the anatomy of the cell structure (Purves et al. 2004).

The ability of neurons or nerve cells to process information is due to the properties of their cell membranes. The synaptic integration is based on the electrical properties of the neuronal membrane. Like other cells membranes, the neuronal cell membranes are made up of lipid bilayer into which various membrane proteins are incorporated. One can classify the membrane proteins either as structural receptors, enzymes, pumps, or channels, although these different classes are

not mutually exclusive. Structural proteins contribute to the maintenance of cellular structure and the formation of connections among neurons. Receptors allow the recognition of specific signals transmitting molecules. Enzymes facilitate chemical reaction in or near membrane. Receptor and enzymes control the production of a postsynaptic signal during transmission at chemical synapses. Pumps, by using metabolic energy, can establish ionic gradients or gradients of other molecules, such as water, across the membrane. Channels allow charged ions and molecules passage through the hydrophobic lipid bilayer of the membrane. The electrical activity in nerve cells results from the interaction between ion pumps and ion channels. Ion pumps and ion channels, working together, generate electrical phenomena such as resting potential, action potentials, and synaptic potential.

Therefore, due to characteristics of the neural membranes, they are capable to establish a voltage difference between the inside and outside of the cells membrane, and they use this voltage difference to generate a neural impulse.

A neural impulse consists of a series of action potentials, in response to a change in the resting membrane potential. To understand the process of neural impulse, it is imperative knowing the electrical bases of the neural excitation.

## Resting Membrane Potential

The presence of ion channels in the cell membrane and proteins, such as sodium-potassium exchange pumps ( $\text{Na}^+/\text{K}^+$  ATPase), allows the separation of ions (mainly  $\text{K}^+$ ,  $\text{Na}^+$ ) in the intracellular and extracellular compartment, generating ionic gradients. This process allows a more negative charge in the cytoplasm than in the extracellular space. This charge separation across the membrane is a form of potential energy, called membrane potential, and the potential difference across the membrane in resting neurons is called resting membrane potential. The resting membrane potential of most unstimulated neurons is  $-70$  mV (millivolts). The resting membrane potential provides energy for the generation of a neural impulse in response to appropriated stimulus. Thus, the resting potential maintains the

membrane of neurons in a condition of readiness for an impulse to occur. The energy of any eventual impulse is stored in the electrochemical gradient across the membrane (Wright et al. 2004).

## Graded Potential

As previously stated, the action potential is the major signal sent down the axon. By contrast, the graded potential takes place at the dendrites and cell body; this potential varies in size and determines whether an action potential will be sent or not. Graded potentials are small changes in membrane potential that are either excitatory (depolarize the membrane) or inhibitory (hyperpolarize the membrane). A certain level of excitatory graded potential must happen at once to depolarize the cell body enough to trigger the action potential (Wright et al. 2004).

## Action Potential

To understand an impulse, we first need to focus on an individual action potential taking place on one tiny segment of the axon membrane, called nodes of Ranvier. These nodes of Ranvier are myelin-free structure in the axonal membrane, where the presence of  $\text{Na}^+$  channels is higher. The action potential starts when the neural membrane is “depolarized,” this means that the membrane potential is reduced to less ( $-55$  mV) than the resting membrane potential of  $-70$  mV. The action potential can be divided into four phases:

1. Threshold potential: positive ions flow into the negative cell, generating a difference, decrease, in the cell's polarity (from  $-70$  to  $-55$  mV). If the cell body gets positive enough that it can trigger the voltage-gated sodium channels found in the axon, then the action potential will be sent.
2. Depolarization: makes the cell less polarized (membrane potential gets smaller as ions quickly begin to equalize the concentration gradients). Proteins called voltage-gated sodium channels at the part of the axon closest to the cell body activate, thanks to the recently

depolarized cell body. This lets positively charged sodium ions flow into the negatively charged axon and depolarize the surrounding axon. We could view the channels opening like dominoes falling down, once one channel opens and lets positive ions in, it sets the stage for the channels down the axon to do the same thing. Though this stage is known as depolarization, the neuron swings past equilibrium and becomes positively charged as the action potential passes through.

3. Repolarization: brings the cell back to resting potential. The inactivation gates of the sodium channels close, stopping the inward rush of positive ions. At the same time, the potassium channels open. There is much more potassium inside the cell than out, so when these channels open, more potassium exits than comes in. This means the cell loses positively charged ions and returns back toward its resting state.
4. Hyperpolarization: makes the cell more negative than its typical resting membrane potential. As the action potential passes through, potassium channels stay open a little bit longer and continue to let positive ions exit the neuron. This means that the cell temporarily hyperpolarizes or gets even more negative than its resting state. As the potassium channels close, the sodium-potassium pump works to reestablish the resting state.

Action potentials work on an all-or-none basis. This means that an action potential is either triggered, or it isn't, like flipping a switch. A neuron will always send the same size action potential. When the neuron is highly excited, it fires off multiple signals, with the rate of neural firing correlating with the intensity of the original stimulus: the more intense the signal, the higher the frequency of action potentials. There is a maximum frequency at which a single neuron can send action potentials, and this is determined by its absolute and relative refractory periods.

Absolute refractory period: during this time, it is absolutely impossible to send another action potential. The gates inactivation of the  $\text{Na}^+$  channels lock shut for a time, and make it so no sodium will pass through. No sodium means no depolarization, which means no action potential.

Absolute refractory periods help direct the action potential down the axon, because only channels further downstream can open and let in depolarizing ions.

Relative refractory period: during this time, it is really hard to send an action potential. This is the period after the absolute refractory period, when the gates are open again. However, the cell is still hyperpolarized after sending an action potential. It would take even more positive ions than usual to reach the appropriate depolarization potential. This means that the initial triggering event would have to be stronger than normal in order to send more action potentials along. Relative refractory periods can help us figure how intense a stimulus is; cells in your retina will send signals faster in bright light than in dim light, because the trigger is stronger (Barnett and Larkman 2007).

Refractory periods also give the neuron some time to replenish the packets of neurotransmitter found at the axon terminal, so that it can keep passing the message along. While it is still possible to completely exhaust the neuron's supply of neurotransmitter by continuous firing, the refractory periods help the cell last a little longer.

Because action potential is forced to "jump" from one node of Ranvier to the next due to the myelin sheath, the conduction of an impulse along a myelinated neuron is called *saltatory conduction*. A similar process occurs in unmyelinated neurons. In these neurons, however, action potentials can occur at all locations along a membrane. Therefore, they occur next to each other. As a result of so many action potentials occurring all along the axon, the transmission of an impulse along an unmyelinated axon is much slower than the saltatory conduction along a myelinated axon (about 0.5 m/s, compared with as much as 120 m/s in a myelinated axon) (Nicholls et al. 2001).

The nerve impulse, generated by action potentials, travels the length of the axon until it reaches the far end, called synaptic terminal (presynaptic terminal). In this structure, the nerve impulses induce the release of chemical messengers (neurotransmitters) that diffuse across the synaptic cleft, taking 0.5–1 ms to reach the next neurons (postsynaptic cell). These chemical messengers bind to specific receptor in the membrane of the

postsynaptic neuron, generate a depolarization of the membrane, and, if the threshold potential is reached, initiate an action potential and continue the nerve impulse.

## Synonyms

[Brain circuit](#); [Neural circuit](#); [Complex arrangement](#); [Complex system](#); [Connectionist network](#); [Interconnected structure](#); [Interconnected system](#); [Neural architecture](#); [Nexus](#)

The expression **neural network** is much more recent than its constituent terms. The adjective **neural** relates to the adjective **neuronal**, from

the noun **neuron** (see the entry “[Neuron](#)” in this encyclopedia). This noun originated with von Waldeyer-Hartz’ (2016) German **neurone**, coined in 1891, likely inspired by the Greek νεῦρον or νεῦρον, meaning “nerve,” which he used as synonymous with **nerve cell**. He proposed it as a technical term for a kind of cell that constitutes brain tissue, marking the birth of the *neuron doctrine* (see Shepherd 2016), the now universally accepted thesis that brain tissue, like any other tissue, consists of *discrete*, individual units called “cells.”

The noun **network** is much older, dating from the 1500s, and is a contraction of the nouns **net** and **work**. Skeat (1910, p. 334) defines **net** as “an implement made of knitted or knotted twine for catching fish” (p. 399), present in Middle English (roughly between 1200 and 1460) as **net** and **netten**. Current uses of **net** in **network** are reminiscent of this sense. The noun **work** is from about the same time but has a more complex etymology. According to Skeat (1910), the term comes from the Middle-English **werk**, meaning “thing done or written” (p. 722) and “to do.” Current usage is reminiscent of this origins, where a network is “an arrangement of intersecting horizontal and vertical lines,” “a number of interconnected computers, machines, or operations,” or “a system of connected electrical conductors” (<https://www.lexico.com/en/definition/network>).

## General Intuitive Initiation

These meanings lead to a very rough, preliminary notion of a neural network as a system of *units* (or elements, nodes, or vertices) that are *mathematical models* of neuronal activity, linked through *connections* (or edges) that are mathematical models of synaptic plasticity (changes in synaptic strength). Some uses of **neural networks** refer to systems of biological, natural, and organic neurons connected through biological synapses (e.g., brain circuits), but I will not follow these uses. In this entry, I will refer only to *theoretical* or *artificial* neural networks and call them just “neural networks” (NNs).

Figure 1 shows a few examples of very small NNs thus defined (I will elaborate some of the technical details in the third section). (NNs in most modeling research are much larger.) There are two types: layered (upper panel) and non-layered (lower panel). In layered networks, the most common, units are arranged into *layers*, depicted here as *columns* of units (it is also common to depict layers as rows). Layered NNs in early modeling had only two layers, input and output (upper left panel), but as I elaborate later, they suffered from critical insurmountable limitations.

An input layer consists of input units (squares) that function as detectors of external environmental

events (in depictions of layers as rows, the input layer is commonly placed at the bottom row). Each layered NN in Fig. 1 has three input units. The output layer consists of output units whose functioning represents a NN's performance or responding, the final stage of a NN's functioning (in depictions of layers as rows, the output layer is commonly placed at the top row).

Most layered NNs also have at least one *hidden* layer (middle upper panel) between the input and output layers, but many NNs have more (right upper panel) and are known as *deep* NNs, which have become quite popular during the last decade. Units in non-layered NNs do not have layers, so in principle any nonspatially contiguous units could

**Neural Network, Fig. 1** Examples of two types of NNs: layered (top panel) and non-layered (bottom panel). In layered NNs, units are arranged into layers depicted here as columns of units. These NNs have at least two layers of units, input and output (upper left panel), but most (middle and right upper panels) include at least one *hidden* layer between the input and output layers. The input layer consists of input units (squares) that detect external environmental events (the layered NNs here have three input units). Computational units are represented as circles. Connections are represented as arrows and typically have

changeable strengths numerically represented as *weights* that change according to a *learning* algorithm. Typically, connections in feedforward NNs are *unidirectional* in that a connection goes *from* a unit *i* to another unit *j*, but not vice versa. Therefore, *i* can affect *j* but not vice versa. In the input-output NN, the input units connect to and affect the output units directly. In contrast, connections in the non-layered NN are bidirectional. In this NN, then, the units are *completely interconnected*. Units in non-layered topologies have no particular arrangement

function as inputs. In the non-layered NN in Fig. 1, for example, I arbitrarily chose three separate units as inputs.

Neural units (circles) function according to a model of neuronal activity in the form of an *activation function*, used to calculate a unit's *activity* or *activation state* at some moment  $t$ . (I depict input units differently because their states are *assigned* according to a training protocol that defines the task a NN is to do.) Connections are depicted as arrows and usually have changeable *strengths* numerically represented as *weights* that change according to a *learning function*. Connections represent abstract, theoretical synapses or synaptic groups and are the means through which units *influence* each other's activation states, depending on the connection weights (the larger the weight, the greater the influence).

In layered NNs, connections are *unidirectional* in that a connection *projects from* a unit  $i$  to another unit  $j$ , such that  $i$  can influence  $j$  but *not* vice versa. In this sense, layered NNs have a layer-to-layer *feedforward connectivity*, for which they are called "feedforward NNs." Typically, this connectivity is *complete* in that all units in one layer connect to all units in the layer immediately adjacent (to the right, in layers depicted as columns). The connectivity of the non-layered NN in Fig. 1 is also complete, but its connections are often *bidirectional*. In this sense, units in these NNs are *interconnected* and, hence, mutually influence one another. I will not speak of this type of NN anymore, to focus on layered feedforward NNs, or just NNs, to abbreviate.

Unit activities *propagate* through connections from inputs to outputs (left to right in layers depicted as columns, as in Fig. 1), directly (without the mediation of other units) in NNs without hidden layers or indirectly in NNs with hidden layers. In the latter, hidden-unit activation states mediate between input and output activation states.

The above suggests a kinship between NN modeling and neuroscience, where NN modeling is *inspired* by brain structure and functioning as studied in neuroscience. This inspiration has taken various forms that differ in its closeness to neuroscientific laboratory data. On one end of this

spectrum, *computational neuroscience* follows the closest inspiration, where models seek to be *realistic* by fitting as accurately as possible experimental data about neuronal activity and synaptic plasticity. These models thus tend to be much more concrete. On the other side of the brain inspiration spectrum, models do not seek to be so accurate and are often called "connectionist." They are much more abstract and simplified than computational neuroscience models.

The two approaches have grown apart, to the point of becoming different, often warring scientific cultures. Computational neuroscientists dismiss connectionist models as too high-level and unconstrained by neuroscientific data, which makes them neuroscientifically invalid. Connectionists complain that computational neuroscience models are too low-level and lack generality, which makes them incapable of capturing psychological phenomena. Both sides have a point, but arbitrating between them raises a very difficult issue I cannot address here: model abstraction is a matter of degree, and it is unclear how much abstraction is too much or too little. I am a psychologist and, hence, partial to connectionist models, so they will be my focus in this entry.

Despite their important methodological differences, both sides share the general intuition that there is an important relation between the brain and "the mind" or "the mental," broadly conceived to include "phenomenal consciousness" (sensory and perceptual experiences), and "cognition," often associated with "intelligence" and "thinking." (I quote all these terms because they lack technical, universally agreed-upon definitions, and I will not even try to give any such definitions here.) This intuition is far from new. It was already present in Ancient Greece, well before the advent of the neuron doctrine and NN modeling.

Most NN modeling has a strong *engineering* or "tech" motivation to solve concrete practical problems. They are legion and include optimization tasks, various types of pattern recognition (face, voice, handwriting, etc.), natural language processing, image compression, marketing, stock prediction, banking-finance, robotics, gaming, self-driving vehicles, and medical diagnosis,

among many others. Tech NN modeling seeks effective efficient problem solutions that require flawless, superhuman performance, more than a *scientific understanding of natural* psychological phenomena and their underlying brain processes.

NN tech research is very important in generating technologies that improve the human condition, but will not be my focus here. Instead, I will focus on the minority of NN modeling, aimed at scientific understanding of behaviors indicative of mental state, process, or condition, as they actually occur and how they relate to brains, independently (without excluding the possibility) of practical applicability. In short, I will focus on *basic* connectionist NN modeling (NN modeling, henceforth). I do not mean to separate sharply between basic and tech research models, only a very fuzzy distinction between models uses. There is considerable overlap between the two kinds of uses. The same model could be used in both ways, and this will be the case of the models I discuss later on.

Before I elaborate, I will step back briefly to give some historical-conceptual context. For this, I will first summarize traditional cognitive science (TCS) as the approach that dominated the field for over a decade, before NN models became a viable alternative. After this, I will dedicate the rest of the entry to the foundations of basic NN modeling and illustrate with a few representative models.

## TCS

TCS had a strong tech motivation from its beginnings in traditional artificial intelligence (TAI) but also sought to understand scientifically human “intelligence.” (This term is very problematic, but its use is widespread, so I will follow suit.) Both fields arose from a series of related papers. In some of them, Church (1936a, b) and Turing (1936–1937) marked the beginnings of computer science as attempts to solve the so-called *Entscheidungsproblem*, German expression for “decision problem.”

The problem originated almost a decade earlier, in relation to *predicate logic*, the part of *modern formal* or *symbolic* logic to formalize the *grammatical structure* (subjects and predicates)

of statements, such as “All humans are mortal,” “Socrates is human,” and “Socrates is mortal,” and valid arguments with them. These three statements are classical examples of the constituents of a class of Aristotelian syllogisms, a kind of deductive (logically valid) argument where the first two are the premises and the third is the conclusion that follows from them. Logical validity in these arguments hinges on the grammatical structure of their statements. Symbols for statements in *propositional* logic ( $p$ ,  $q$ , etc.), another part of symbolic logic, conceal this structure and, hence, are unsuitable to formalize such arguments. Propositional logic only allows formalizing arguments whose logical validity does not hinge on symbolizing this structure.

In essence, the Entscheidungsproblem asks whether statements of a certain class in first-order predicate logic are *decidable*. That is to say, does an *effective method* or *algorithm* exist to decide whether any such statements is or not *tautological* (i.e., *necessarily true* or true *in all logical possibilities*)? Propositional logic has an algorithm, known as the *truth table*, to decide whether any statement in this logic is tautological (or whether any argument in this logic is valid). This algorithm was key to the origins of NN modeling, as I elaborate in the third section.

To solve the Entscheidungsproblem, Church and Turing formalized the notion of an algorithm. They proposed independently different but equivalent formalizations, effective  $\lambda$ -calculability and computability, respectively. With these formalizations, the authors demonstrated that the Entscheidungsproblem was unsolvable, for  $\lambda$ -noncalculable (in Church’s formalization) and noncomputable (in Turing’s formalization). These results led to the general Church-Turing hypothesis that any task doable through a finite sequence of rules is  $\lambda$ -calculable or computable. In particular, everything calculable is  $\lambda$ -calculable or TM-computable and vice versa.

## Turing Machines

The most influential formalization was Turing’s definition of computability (or not) in terms of

what he called an “automatic machine” and Church (1937) called “Turing machine” (TM). Figure 2 depicts a general informal sketch of a TM as often characterized today. It consists of left/right (arrows) moving read/overwrite head (trapezoid) and a two-way tape divided into indefinitely but finitely many cells holding one *token* of a prespecified symbol *type* from a finite set of symbol *types*  $\{Y_i, Y_j, Y_k, \dots\}$ . The required set depends on the task the TM is to do. Different tasks may or may not require different symbol-type sets, but the general notion defines all TMs and gives them their *symbolic* character.

Figure 2 shows three cells with symbol variables  $y_i, y_j,$  and  $y_k$  that can hold one *token* of the same or different members of the symbol-type set at a time  $t$ . The tape may have any required *finite* length as dictated by the task of interest. Different TMs could thus vary in the length of their tapes (ellipses). Also defining of a TM (not shown in the figure) is the set of its *possible internal states*. A TM can be in one and only one of these states at  $t$ , according to a *transition* table that instructs what state the TM should be in and what its head should do at  $t$  (read, write, move to the left, or move to the right). All this depends on the machine’s internal state and the symbol in the cell where the head is at  $t$ .

Different TMs can be defined for different computational tasks, but it is also possible to define a *universal Turing machine* (UTM) that can in principle do the tasks all different TMs can do. This possibility led to a technological breakthrough during the 1940s: the development

of *physical implementations* or *realizations* of a UTM that marked the beginnings of electronic personal computers, as we know them today. These implementations added components such as storage memory and a central processing unit (CPU) that do the actual computations in real time while the computer is on.

Three features of a UTM are central to this story. First, computation in a UTM is *symbolic* in nature: a UTM is defined partly by a set of symbols. Second, a UTM’s functioning is inherently (theoretically and physically) *serial* because it can be in one and only one internal state at a time. A UTM’s functioning thus consists of a *succession* of input – internal state – output triplets across different times, where different triplets *imply* different moments. Third, in physical implementations of a UTM in digital computers, the CPU makes computations *centralized*.

## The Imitation Game

The use of a UTM to model human intelligence began with Turing’s (1950; further references to Turing will be to this entry) other widely influential paper. In this paper, he used his concept of a UTM to reformulate the question of whether machines could think. He called his reformulation “the imitation game” or “question-and-answer method” (p. 435), more familiarly known as the “Turing test” (TT). I will summarize it very briefly, as this encyclopedia includes an entry for this topic (see ► “Turing Test”).

In a simple modern version, the TT involves human “interrogators” or participants engaging in a question-and-answer conversation with different input-output interfaces (e.g., computer keyboards and monitors). In separate rooms, confederate humans control one interface, and a UTM computer running a conversation app controls the other. The participants know this but not which is which, and their task is to choose. If a certain agreed-upon percentage of participants choose the UTM, it “passes” the TT or plays the imitation game “satisfactorily” or “well,” as Turing put it.

Turing proposed to replace the question of whether machines could think with the question

**Neural Network, Fig. 2** General informal sketch of a TM. Trapezoid: Left/right moving (arrows) read/overwrite head.  $y_i, y_j, y_k$ : Symbol-token variables. Squares: A tape’s cells that hold symbol tokens. The length of the tape is given by the number of squares, which can vary across different specific machines (ellipses), depending on the task the machine is expected to do, but must be finite. At any moment, the head can move one cell to the left or to the right, depending on the symbol in the current cell and the machine’s current state

of whether a UTM physically implemented in an electronic digital computer could play the imitation game well. He predicted that "... in about fifty years' time," computers would be sufficiently powerful to play the imitation game so well that "one will be able to speak of machines thinking without expecting to be contradicted" (p. 442), if a sufficiently clear and precise meaning of "thinking" arose (which he also predicted).

This prediction remains unfulfilled, at least in the way Turing envisioned his imitation game, which focused on *general* intelligence in *English-speaking adults*. A reason has been his lack of detail on the game's rules. The game analogy suggests clear, detailed, precise rules that leave little doubt about how to play. Games as different as chess, go, soccer, baseball, basketball, poker, and Monopoly© share this key feature, but not Turing's game, as innovative and inspiring as it was. This led to different ways to fill in the details, and there still is no agreement over which one is the best one.

## Logical Problems with TCS

In the meantime, I wonder counterfactually (a common exercise in basic science) *what if* a UTM passed the TT. With this exercise, I seek to reflect on how fulfillment of Turing's prediction *would* advance scientific understanding of human thinking. The answer from TCS arises from its core hypothesis that human thinking *is* UTM computing. A UTM passing the TT would thus advance such understanding by giving empirical support to this hypothesis. The standard rationale for this answer in TCS and TAI hinged on the assumption that intelligent behavior was a *sufficiently reliable* indicator (ideally, a *deterministic effect*) of covert functioning to warrant inference of a similarity in the latter from a similarity in the former. (It is unclear to me whether Turing followed this rationale. He likely viewed the covert workings of humans and UTMs that passed the TT as thinking, but it is not obvious that he viewed the two covert workings as being of the *same kind*.)

This assumption, however, is very debatable. A major issue arises from the widely held view

that thinking crucially involves *understanding* (Turing hinted this relation, but did not delve into it). In ordinary English, the adjective **thoughtful** is synonymous with **understanding**, often defined as "the power of abstract thought." Math teachers often admit the possibility that high schoolers could be quite good at solving certain standard high-school math problems without knowing their underlying principles. High schoolers can multiply without knowing that multiplications are abbreviated sums. They can also solve standard high-school algebra problems without knowing abstract algebra and standard high-school geometry problems using the Pythagorean theorem without knowing how to *prove it logically*.

Intuitively, understanding in these considerations includes knowing something *additional* about a task, such as its foundational principles, which is neither necessary nor sufficient for doing it correctly. To this extent, passing the TT does not even entail thinking period, let alone that human thinking is like machine thinking. At best, they only *indicate the possibility* of thinking, a much weaker, hypothetical proposal. A high schooler *could* be excellent at solving standard high-school problems with the Pythagorean theorem *and* know how to prove it logically, but the former does not *entail* the latter nor vice versa: someone could know how to prove the theorem logically but be very bad at using it in practical situations without the aid of a calculator.

In sum, there can be thinking behavior without covert thinking and vice versa. Therefore, even the existence of *humans* who pass the TT does not imply that they think. Searle (1980) famously argued this implication in his widely discussed Chinese room thought experiment. In this experiment, a human is entirely ignorant of Chinese in a room with access to an enormous database of correspondences among different Chinese expressions. This human does not need to know or understand any Chinese at all to use the database. A Chinese-speaking user outside introduces into the room a paper or card with something written in Chinese; the person inside the room searches for this expression in the dictionary, prints the proper reply stipulated by the dictionary, and sends it back out to the user, who understands the reply as meaningful.

Searle's point was that the person inside the room passes the TT for a meaningful Chinese conversation, but does not *understand Chinese*. Passing the TT, then, is not sufficient for thinking, a conclusion against TCS' core hypothesis that human thinking is TM computing ("strong" AI, as Searle called it), nor is it necessary, if widespread talk of *nonhuman* animal thinking is to be admissible. Turing envisioned his game as a linguistic task, so nonlinguistic creatures cannot play it, which precludes such talk.

All this suggests that thinking behavior does not warrant a strong argument by analogy of the kind behind the TCS' core hypothesis. Further support of this outcome came from Putnam's (1988) rejection of his own *functionalism* about the mind (Putnam 1960). His main hypothesis was that a type of mental state was a type of causal role that mediated a type of input-output relation. To do significant explanatory and predictive work, this hypothesis requires that computational states *individuate* mental states *unequivocally* and vice versa. However, Putnam concluded that this requirement was unfeasible in principle: different types of computational states could constitute the same type of mental state, and the same type of computational state could constitute different types of mental states. Both possibilities reduce functionalism's explanatory and predictive power.

Specifically, Putnam realized that being UTM computational was not exclusive to the mental, an obvious possibility he and his followers failed to appreciate (and many still do today). The old Galilean adage that "the book of nature is written in mathematical language," and, centuries earlier, the Pythagoreans, anticipated the possibility. Taken literally, this adage leads to *pancomputationalism*, the thesis that *all* reality is computational in nature.

The extreme version of this thesis, UTM-pancomputationalism, asserts that the universe is one giant UTM. The rationale behind this version is that all *true* mathematical scientific models are computational and, hence, programmable and executable by UTMs, and crucial to what makes them true is that the phenomena they model are UTM-computational in nature. However, these include myriad phenomena that are not mental in

any standard sense of the term, such as the Moon's revolution, billiard balls colliding and falling, water flowing inside a pipe, the shear resistance of concrete beams, crystallization, hurricanes, and radioactive decay, among many others.

If TCS researchers insist that UTM-computing is exclusive to the mental, they would have to restrict UTM-computing to the type of covert functioning that supposedly causes thinking behavior, but it is not obvious how to justify this restriction. If they embrace UTM-pancomputationalism and maintain UTM-computing is exclusive to the mental, they fall back to *panpsychism*, the thesis that all reality, the above phenomena included, are literally mental in nature, a very inconvenient outcome. The middle position, to accept UTM-pancomputationalism but view the mental as a special kind of UTM-computing, avoids this outcome but also lacks compelling justification.

## Connectionist Cognitive Science (CCS)

TCS thus seems to be sufficiently problematic to deserve a healthy dose of skepticism, and it has: TCS is no longer dominant in cognitive science, nor is TAI dominant in AI tech research. The obsession over the TT might have contributed to this, so lessening it might benefit future TCS and TAI research. NN modeling offers a different (not necessarily opposite) approach, often labeled "connectionist cognitive science" (CCS). Its tech manifestation is connectionist AI or CAI. The term **connectionism** also labels certain proposals in early psychology of learning (see ► ["Learning"](#) in this encyclopedia), but here I use it only to name the hypothesis that drives NN modeling.

Very succinctly and roughly, the main guiding hypothesis in CCS is this: NN models explain the mental better than UTMs do. The key reason is the NN models' greater emphasis on the mental as it naturally occurs, with its flaws and physical constitution. This emphasis contrasts sharply with Turing's focus on idealized perfect intelligent behavior in a UTM ("By definition ... we can truly say that 'machines can never make mistakes'," Turing 1950, p. 449). He thus excluded mistakes, even physical constitution, as

inessential to thinking (the latter exclusion was a major inspiration for functionalism about the mind). Thinking behavior remains a criterion in CCS, but mistakes and physical constitution are essential. CCS research has shown a greater interest in nonsymbolic behavior, allowing for a broader, more flexible concept of the mental that includes nonhuman animals.

Methodologically, computational modeling consists in *finding numerical solutions* to a model's equations. In most NN models, the equations are the activation and the learning functions. A common way to do this is to code the equations in a programming language and use the resulting application to run *simulation experiments* in electronic computers (there also are robotic, hardware applications). The use of electronic digital computers in this way is mainly practical: they are much faster and more reliable at doing the required calculations. This use, however, is quite suggestive when comparing NNs to UTMs.

## NNs and UTMs Compared

Conventional wisdom has it that NNs and UTMs are incompatible. It is customary, for instance, to view neural-network functioning as nonsymbolic, parallel, and distributed and contrast these features respectively to the symbolic, sequential, and centralized character of a UTM's functioning. (I prefer to speak of **functioning**, which relates more intuitively to **working**, than **representation** and **processing**; **representation** is infamously difficult to define technically in a way acceptable to most users; **processing** promotes the use of information theory, which is optional and complicates the matter considerably.)

The specialized literature is not entirely clear in these distinctions, but the intuitions behind them seem to be more or less like this. Nonsymbolic functioning is *analog* or *quantitatively continuous* in nature, where quantities are real numbers rather than symbols as traditionally conceived in linguistics (marks with certain conventional qualitative morphologies, connotations, and denotations). Parallel functioning consists in the simultaneous operation of a NN's constituent parts (units and

connections). Distributed functioning refers to their equivalent functioning.

But then again, these features are not as incompatible as they seem to be, in various respects. An obvious one is that all NN models are computational. Therefore, they are programmable and executable in UTM electronic computers that do numerical calculations in the binary system. The symbol set of this UTM is  $\{0,1\}$ , where "0" means "OFF" and "1" means "ON," in reference to the possible states of electronic switches in today's computers. The same set of symbols made symbolic logic key to the origins of NN modeling as well albeit in quite a different way, as I clarify shortly.

McCulloch and Pitts (1943) anticipated the UTM-NN affinity in what many regard as the first NN paper (not cited by Turing):

... every net, if furnished with a tape, scanners connected to afferents, and suitable efferents to perform the necessary motor-operations, can compute only such numbers as can a Turing machine ... each of the latter numbers can be computed by such a net .... (p. 129)

Relatedly, Siegelmann and Sontag (1991) proved that at least one kind of neural network exists that can simulate a UTM. Moreover, for decades there have been efforts to build *hybrid, neurosymbolic* models that combine NN quantitative and TM-style qualitative functioning (<https://www.microsoft.com/en-us/research/blog/next-generation-architectures-bridge-gap-between-neural-and-symbolic-representations-with-neural-symbols/>).

NNs resemble TMs also in that NN functioning is *physically* sequential. NNs' functioning is parallel only theoretically, depending on how they conceive time. In most NN models, like TMs, time is conceived as *discrete*, consisting of whole moments, times, epochs, or occasions (symbolized as  $t_1, t_2, \dots$ ) of *arbitrary* (often unspecified) but *nonzero* duration. NN functioning in these models is parallel only in that calculations occur in the same *theoretical* moment, but all moments have temporal extension, no matter how short, so calculations must be physically sequential.

NNs and UTMs, then, are less sharply different than often believed, although they still differ in

important respects. Perhaps the distributed-centralized distinction is more differentiating: it is unclear how NNs and UTMs are *conceptually* comparable in this regard. A related feature also viewed as distinctive of NNs is *graceful degradation*, a gradual performance deterioration with the gradual loss of units (provided a sufficiently large NN). Human brains have this feature: they can lose thousands of neurons daily to natural death without significant performance deterioration. In contrast, losing just one part, the CPU, would completely shut down a UTM computer.

In the introduction, I anticipated the defining feature of NNs that differentiates them more clearly from UTMs: automated learning. The difference is not one of *theoretical possibility* but *emphasis* (or lack thereof). Turing discussed the issue of learning in addressing the objection that a UTM could not think in ways that deviated from what it has been programmed to do. He dedicated the last section of his 1950 paper to this discussion, under the heading *Learning Machines* (pp. 454–460). His discussion relied heavily on rather convoluted similes, but my understanding is as follows.

He speculated that a UTM could learn *in principle* by having a changeable transition table where the rules of operation had “only an ephemeral validity” (p. 458), but did not *need* to *in practice*, for two reasons. One, his idealization of thinking behavior and thinking in the imitation game presupposed maximally effective and efficient means of acquiring the necessary knowledge to play the game well. Two, he viewed learning (and evolution) as too inefficient and uncertain a process to guarantee perfect results, as it inevitably involved randomness. He thus put learning aside, at least as a *temporary strategic simplification*, perhaps even as inessential to thinking. All this made TCS and TAI researchers indifferent to learning, which might have fed their adoption of *nativism* (the thesis that the mental is innate) and perhaps vice versa.

Not so in NN modeling. Although NNs could in principle work as expected without any learning (as I illustrate next), this possibility quickly became unviable in practice. I suspect that this (combined with a scientific interest in natural

intelligence) drove early NN modelers to focus on learning and give it a central role. This focus was compatible with (in fact, supported) the inspiration on brain structure and functioning, which historically came first.

## Some Fundamentals

As anticipated in the introduction, the basic concepts of NN modeling are task, neural unit, activation, connection, and weight. I now illustrate them the first and simplest NN model: the McCulloch-Pitts (MCP) model. It has more historic than scientific interest, but it sets some theoretical foundations of NN modeling. It also shows how symbolic logic was at the root of NN modeling although in a different way: using propositional logic as a model of brain functioning (What of *predicate* logic? This question motivated neurosymbolic models.) This use arose from the *all-or-none law* of neuronal functioning. According to this law, a neuron is either completely active or completely inactive, a key intuition that defined NN modeling from its beginnings.

Based on this law, MCP viewed neuronal functioning a “factually equivalent to a proposition” (p. 117), meaning that unit activations are *functionally analogous* to truth-values of standard bivalent propositional logic. A standard way to express this analogy is to symbolize the active (or ON) state as 1 and the inactive (or OFF) state as 0. With this symbolism, it is common to express the MCP model as the following activation function (MCP did not formulate it quite like this):

$$a_j = \begin{cases} 1, & x_j \geq \theta \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

where  $a_j$  denotes the activation *state* *act* of target neural unit  $j$ , 1 and 0 denote “active” (or “ON”) and “inactive” (or “OFF”), respectively, and  $\theta$  denotes a threshold. Equation 1 is a *conditional* or *decision function* in that reads as follows: unit  $j$  is *either* active (its activation state is (1) *if*  $x$  is equal to or greater than ( $\geq$ )  $\theta$  *or* inactive (its activation level is 0) *if*  $x$  is less than ( $<$ )  $\theta$ . (Some use  $>$  and  $\leq$  instead, but I prefer the

present way because  $\geq$  captures *reaching*  $\theta$  as sufficient for neuronal firing.) It is also common to define  $x_j$  algebraically as

$$x_j = \sum_{i=1}^n a_i w_{i,j}, \quad (2)$$

where  $i$  denotes an *afferent* unit *connected* to  $j$ ,  $n$  the total number of afferents connected to  $j$  (at least one),  $a_i$  denotes the activation state of afferent unit  $i$ , and  $w_{i,j}$  denotes the weight of the connection from  $i$  to  $j$ .

In *linear algebra* (the part of mathematics about vectors and matrices, widely used in NN modeling), Eq. 2 is a product of two *vectors* (sets of values ordered usually as columns) with the same number of members. The two vectors in Eq. 2 are the vector of *input* activations and the vector of weights of the corresponding connections from the afferents. This product expresses a central assumption of all NN modeling: the relation between neuronal activations and synaptic strengths can be mathematically described as *linearly multiplicative*.

Equation 1 is a binary threshold or step activation function, where, following the all-or-none law, a unit's activation state at  $t$  could be either 1 or 0. It is the simplest activation function in NN modeling, but it has important limitations, as I show later. Before I do, I next illustrate very simply how the MCP model works, following modern depictions of it.

**A toy example.** The first steps in NN modeling are to define the task of interest and design a NN for this task. The usual order is to first define the task as clearly and precisely as possible and then design a NN that could do it (a NN designed for a certain task may or may not work with others). As tasks become increasingly complex, modelers need to test several NNs to find a suitable one, but here I will focus on very simple tasks and NNs. They are of very limited use for scientific understanding (let alone practical applications) but constitute theoretical foundations of basic NN modeling.

The tasks are defined by input-output relations functionally analogous to *truth tables* in

propositional logic (specifications of all the possible truth-values for any given proposition). In these tasks, the inputs are *possible activation states* of a NN's input units, and outputs are the *expected, desired, or target* output activation states for different possible input activations. The simplest truth table defines the *negation* of one proposition  $p$ , often symbolized as  $\sim p$ , where  $\sim p$  is false when  $p$  is true and vice versa. The input-output relation that defines the analogous task for a NN stipulates target output activation states of 0 and 1 for input activation states of 1 and 0, respectively.

The minimal MCP network for this task is the smallest NN possible, consisting of one input unit connected to one output unit. This network can do the task if at least one connection weight and one value of  $\theta$  exist that satisfy the task's definition, where the *actual* NN's output activation state, computed using Eq. 1, must equal the expected output activation state stipulated in the task. It is possible to demonstrate this algebraically by determining whether the system of *linear Boolean inequalities* for the task is *solvable*. They are linear inequalities because of Eq. 1, as explained above and Boolean after Boole (1847), who created this kind of algebra. Let  $w$  denote the weight of the NN's connection. The system for the negation task consists of two inequalities,  $1w < \theta$  and  $0w \geq \theta$ , or, simplifying,  $w < \theta$  (because  $1w = w$ ) and  $0 \geq \theta$  (because  $0w = 0$ ), which is solvable. There are infinite solutions, but one, for example, is  $\theta = 0$  and  $w = -0.1$ .

A larger set of tasks are functionally analogous to all possible truth tables for two propositions  $p$  and  $q$ . There are  $2^{2^2} = 16$  such tables the base and first power are the number of truth – values the second power is the number of propositions, all with  $2^2 = 4$  rows, where the power is the number of propositions. Among these tables, there are those that define some *logical connectives* taught in introductory textbooks of symbolic logic.

To illustrate, I will define only three tasks functionally analogous to the truth tables for the conjunction (&, “and”), inclusive disjunction ( $\vee$ , “and/or”), and conditional ( $\rightarrow$ , “if... , then...”) operators. Table 1 shows the three tasks

**Neural Network, Table 1** Tasks functionally analogous to the truth tables for conjunction (&, “and”), inclusive disjunction ( $\vee$ , “and/or”), and material conditional ( $\rightarrow$ , “if..., then...” or “only if”) in propositional logic. The rows of columns labeled as  $a_1$  and  $a_2$  specify all possible input activations, common to all the tasks. A pair of possible input activation states is an input *pattern* or *vector*. The rows of the other columns specify the *desired* or *expected* activations of the neural unit that will function as the output unit

| $a_1$ | $a_2$ | $a_1 \ \& \ a_2$ | $a_1 \ \vee \ a_2$ | $a_1 \ \rightarrow \ a_2$ |
|-------|-------|------------------|--------------------|---------------------------|
| 1     | 1     | 1                | 1                  | 1                         |
| 1     | 0     | 0                | 1                  | 0                         |
| 0     | 1     | 0                | 1                  | 1                         |
| 0     | 0     | 0                | 0                  | 1                         |

compressed into one table (the order of the rows makes no theoretical difference). The input-output relations that define these tasks consist of the first two columns and any one of the other columns. The first two columns specify all the possible input activation states, common to all the tasks, where a pair of possible input activation states is an input *pattern* or (more mathematically) *vector*. The other columns specify the target output activations for the corresponding input pattern.

The tasks differ only in the target output activation states. For example, the first row for the & task stipulates that the NN’s output unit should be active (have an activation state of 1) whenever its two inputs are active but inactive (have an activation state of 1) whenever one or both inputs are inactive. All the tasks stipulate only two possible output activations, either 0 or 1. This stipulation illustrates the simplest *classification* task, which requires a sharp discrimination between two categories of possible input patterns.

As the tasks suggest, the minimal NN for them needs two input units connected to one output unit. Tasks that are more complex would require larger minimal NNs, and this illustrates how differences in *basic* structural constitution or architecture *define* NN modeling. (All UTM computers have the same architecture.) Figure 3 depicts an example of this NN, labeled as MCP1. It is a three-unit NN with two input units (squares labeled as 1 and 2, where the 1 does not mean the same as the 1 for active) that form the input

**Neural Network, Fig. 3** MCP1, minimal NN necessary to do the tasks defined in Table 1. 1, 2: Input units that form the input layer. At  $t$ , both can be active, one active and the other inactive, or both inactive. 3: Neural output unit.  $a_1$ ,  $a_2$ ,  $a_3$ : 1’s, 2’s, and 3’s activations at  $t$ .  $a_1$  and  $a_2$  are not calculated but assigned by sampling input patterns or vectors (pairs of input activations from the rows of the first two columns of Table 1).  $a_3$  denotes MCP1’s *actual* output activation, calculated with Eq. 1, where  $j = 3$  and  $n = 2$  in Eq. 2. Different input and/or output activations occur at different times. MCP1 has two connections, one from Unit 1 to Unit 3 and the other from Unit 2 to Unit 3.  $w_{1,3}$ ,  $w_{2,3}$ : Connection weights, where the subindexes denote the units

layer and connect to one neural unit (circle labeled as 3) that functions as the output unit. For MCP1, then  $n = 2$  and  $j = 3$  in Eq. 2. MCP1 has two connections, one from Input Unit 1 to Unit 3 and one from Input Unit 2 also to Unit 3. Their weights can be labeled as  $w_{1,3}$  and  $w_{2,3}$ .

MCP1 simulates a *spatial structure* that *persists through time* (no neural development), for all possible input and output activations shown in Table 1. Thus, 1 labels the *same* input unit in different moments; 2 labels a *spatially* separate input unit but the same one in different moments; and 3 labels yet another spatially separate unit but the same one in different moments. As an output unit, 3 is also *functionally* different from 1 and 2, which are input units. For simplicity, I will ignore the time variable and assume that all unit activations and connection weights take particular values at a present theoretical moment  $t$  of constant but indefinite duration. Assume that different activations occur at different moments. In contrast to MCP, I will not assume a delay between input and output activations. In this sense, MCP1’s functioning is parallel *in theory*.

MCP1 can do these tasks if there is at least one set of values for  $w_{1,3}$ ,  $w_{2,3}$ , and  $\theta$  that allow MCP1 to “respond” (have the expected output activation) in *all* the ways specified by the task. It is possible

to determine this algebraically by defining the system of linear Boolean inequalities for each task. Table 2 shows the systems for the three tasks depicted in Table 1.

As before, I simplified by showing only weights multiplied by 1. The three systems are solvable. For example,  $\theta = 0.4$ ,  $w_{1,3} = 0.2$ , and  $w_{2,3} = 0.3$  solve the system for  $\&$ , whereas  $w_{1,3} = 0.4$ ,  $w_{2,3} = 0.5$ , and  $\theta = 0.3$  solve  $\vee$ . Therefore, MCP1 can also do both tasks, as well as  $\rightarrow$  (e.g.,  $\theta = 0.0$ ,  $w_{1,3} = -0.1$ , and  $w_{2,3} = 0.3$  solve the inequality system for this task).

A common geometrically equivalent way to say all this is that these tasks are *linearly separable*. That is to say, there is at least one straight line (defined by a linear function) that separates the 0 from the 1 expected output activations in a Cartesian coordinate system. Figure 4 illustrates this feature for the three tasks with hypothetical lines, where the black (0, analogous to a dark, unlit bulb) and white (1, analogous to a white, lit bulb) dots represent the possible expected

outputs. Most of the rest of the 16 tasks suitable for MCP1 are linearly separable in this sense.

**The problem.** An exception central to this story, reported by Minsky and Papert (1988) in a widely influential book, is the *exclusive disjunction* task, often symbolized as  $\vee$  in propositional logic but more familiarly known in the NN literature as XOR. This task requires the NN’s output unit to be active whenever any of its input units is active but inactive whenever both inputs are either active or inactive. Table 3 depicts this task with its system of linear Boolean inequalities.

This system is unsolvable. The last row requires  $\theta$  to be positive, which means that both weights must also be positive (to satisfy the inequalities of the second and third rows), but the inequality of the first row requires their sum to be less than  $\theta$ . No set of values for  $w_{1,3}$ ,  $w_{2,3}$ , and  $\theta$  can satisfy all of these requirements. Therefore, MCP1 cannot do this task nor the biconditional task, where the target output activation state is 1 for the (1,1) and (0,0) and 0 for the (1,0) and

**Neural Network, Table 2** Linear Boolean inequality systems for the tasks defined in Table 1, simplified by leaving only weights that multiply by 1 and omitting this

value. The systems differ only in the  $\geq$  (for expected output activation states of 1) and  $<$  relations (for expected output activation states of 0), and all are solvable

| $a_1$ | $a_2$ | $a_1 \& a_2$ | Inequalities                    | $a_1 \vee a_2$ |                                 | $a_1 \rightarrow a_2$ |                                 |
|-------|-------|--------------|---------------------------------|----------------|---------------------------------|-----------------------|---------------------------------|
| 1     | 1     | 1            | $w_{1,3} + w_{2,3} \geq \theta$ | 1              | $w_{1,3} + w_{2,3} \geq \theta$ | 1                     | $w_{1,3} + w_{2,3} \geq \theta$ |
| 1     | 0     | 0            | $w_{1,3} < \theta$              | 1              | $w_{1,3} \geq \theta$           | 0                     | $w_{1,3} < \theta$              |
| 0     | 1     | 0            | $w_{2,3} < \theta$              | 1              | $w_{2,3} \geq \theta$           | 1                     | $w_{2,3} \geq \theta$           |
| 0     | 0     | 0            | $0 < \theta$                    | 0              | $0 < \theta$                    | 1                     | $0 \geq \theta$                 |

**Neural Network, Fig. 4** Linear separability of the  $\&$  (left panel),  $\vee$  (middle panel), and  $\rightarrow$  (left panel) tasks, using hypothetical lines. Possible input activations  $a_1$  and  $a_2$  are depicted in the horizontal and vertical axes, respectively.

The expected outputs 0 and 1 are depicted as a black dot (representing a dark, unlit bulb) and a white dot (to represent a lit bulb), respectively

**Neural Network, Table 3** A task MCP1 cannot do, known as XOR (symbolized as  $\vee$ ) and functionally analogous to the truth table that defines exclusive disjunction in propositional logic

| $a_1$ | $a_2$ | $a_1 \vee a_2$ | Inequalities                 |
|-------|-------|----------------|------------------------------|
| 1     | 1     | 0              | $w_{1,3} + w_{2,3} < \theta$ |
| 1     | 0     | 1              | $w_{1,3} \geq \theta$        |
| 0     | 1     | 1              | $w_{2,3} \geq \theta$        |
| 0     | 0     | 0              | $0 < \theta$                 |

(0,1) input patterns. Tasks like these are *linearly inseparable* in that no single straight line separates the 0 from the 1 target outputs. Figure 5 illustrates this feature for  $\vee$  and how such separation requires at least two straight lines or a nonlinear (curved) function.

**Learning as Automated Weight Search: The Perceptron**

The above example demonstrates mathematically that MCP1 cannot do the  $\vee$  task. (I did not demonstrate it for the biconditional.) MCP1 can do all the remaining tasks (I only demonstrated it for three). The example’s simplicity facilitated specifying the required inequalities systems in table form (as in Tables 2 and 3), determining by visual inspection if they had a solution, and finding specific solutions. The example thus illustrates how a NN can do a task correctly without learning, in virtue of a human user (myself) finding weights that allowed for this.

The same applies to tasks and MCP NNs that are more complex, but it quickly becomes unviable, as the numbers and sizes of inequality systems grow exponentially with the number of input units. For example, adding just 1 input unit to MCP1 would result in  $2^3 = 256$  possible systems, each one with  $2^3 = 8$  inequalities. It would be very difficult to specify all of them in table form and determine by visual inspection which ones are solvable (never mind finding particular solutions).

One way around this problem is to use a *learning algorithm, function, or rule* to *automate* the search for weights that allow an MCP NN to do a task. MCP did not include a learning rule, but

**Neural Network, Fig. 5** Linear inseparability of the  $\vee$  task. The input-output relation that defines this task makes it impossible for a single straight line to divide the 0 from the 1 expected output activations. The separation can be achieved with two linear functions or a nonlinear function. Possible input activations  $a_1$  and  $a_2$  are depicted in the horizontal and vertical axes, respectively. The expected outputs 0 and 1 are depicted as a black and a white dot, respectively

Rosenblatt (1958) did. He called the resulting model “the perceptron” and characterized it as taking the “empiricist or ‘connectionist’ position” (p. 397), in opposition to the aforementioned nativism in TCS, implied by rationalism. Such opposition indicates a fundamental *epistemological* disagreement between TCS and CCS.

Rosenblatt formulated his model in terms that were more psychological and neuroscientific, in an effort to model how learned behavior and its brain substrates actually occurred. He strived to distance the model from the tidiness of symbolic logic (and TAI, although he did not cite Turing) and embrace the messiness of natural biological systems by formulating it “in terms of probability theory rather than symbolic logic” (p. 388). (The two are not mutually exclusive, as Carnap 1950, showed in his characterization of inductive logic using symbolic logic as a foundation of probability theory). The probabilistic aspect referred to “random connections” (p. 387), “random stimuli” (p. 405), and response probabilities given different stimuli. (As will become clear below, the learning rule, like the activation rule in Eq. 1, is deterministic.)

In identifying associations with connections, he anticipated an affinity with associationism in the psychology of learning but argued his model was more parsimonious, verifiable, explanatorily powerful, and general than models proposed by

learning psychologists of the time. He also concluded that “the memory of a perceptron is *distributed*” (p. 405), anticipating a defining feature of the connectionist concept of memory, but contrary to standard practice today, he did not speak of connections as representing synapses or weights as representing synaptic strengths (he used none of these expressions). Instead, he identified connections with “association cells” and postulated construct  $V$  as the value of an association cell that could represent “an amplitude, frequency, latency, or probability of completing transmission” (p. 391).

His mathematical formulation of the rule to change  $V$  was quite complex, but it is standard practice today to formulate it more simply and intuitively for a single binary output unit, as the following algorithm:

1. Choose an input *pattern* (vector of possible input activations) randomly.
2. Calculate the real activation of the output unit (according to Eq. 1).
  - a. If the real activation is correct (i.e., equals the target output activation), return to Step 1.
  - b. If incorrect and the real activation is 0, add each input activation to its corresponding weight.
  - c. If incorrect and the real activation is 1, subtract each input activation from its corresponding weight.
3. Return to Step 1.

This cycle is repeated until no weight changes for all the task’s possible input patterns. This repetition brings the temporal dimension into play, which I had ignored before, but now, for the sake of clarity, I will indicate by adding a temporal subindex  $t$  to activations and weights, where  $t$  denotes the run number of the cycle. For MCP1, then, the new notation is  $a_{1,t}$ ,  $a_{2,t}$ , and  $a_{3,t}$  for the activations, and  $w_{1,3,t}$  and  $w_{2,3,t}$  for the weights. Before running the algorithm, we need some *initial* weights. These can be randomly assigned, but as a conveniently simple example, assume that for MCP1 are  $w_{1,3,1} = 1.2$  and  $w_{2,3,1} = 1.3$ . Also assume, as before, that  $\theta = 0.4$  (this value remains constant across different

runs of the algorithm, so it does not need the time subindex).

For the & task, these weights satisfy  $w_{1,3,1} + w_{2,3,1} \geq \theta$  (fourth column, first row of Table 4, with the time subindex added, to indicate the first moment or run of the loop) and  $0 < \theta$  (fourth column, last row of Table 4), but neither  $w_{1,3,1} < \theta$  nor  $w_{2,3,1} < \theta$ . Using Eq. 1, these weights result in  $a_{3,1,1} = 1$ , the incorrect output activation for ( $a_{1,1} = 1$ ,  $a_{2,1} = 0$ ) and ( $a_{1,1} = 0$ ,  $a_{2,1} = 1$ ). In this case, the above algorithm stipulates going to Step 2c. If  $a_{1,1} = 1$  and  $a_{2,1} = 0$ , 2c instructs that  $w_{1,3}-1 = 1.2-1 = 0.2$  and  $w_{2,3}-0 = 1.3-0 = 1.3$ . This change in  $w_{1,3,1}$  ( $w_{2,3,1}$  did not change) means that MCP1 learned to satisfy  $w_{1,3,1} < \theta$ . For the next run ( $t = 2$ ), suppose that  $a_{1,2} = 0$  and  $a_{2,2} = 1$ . The algorithm instructs us to go to Step 2c again, instructing that  $w_{1,3,2}-0 = 0.2-0 = 0.2$  (using the new value of  $w_{1,3,2}$ ) and  $w_{2,3,2}-1 = 1.3-1 = 0.3$ . This change in  $w_{2,3,2}$  means that MCP1 learned to satisfy  $w_{2,3,2} < \theta$ .

I was able to use the algorithm manually, thanks to the example’s simplicity. In tasks and networks that are more complex, it is more viable to code the algorithm in a programming language and run the resulting application on a computer, for an automatic, fast, reliable weight search. This automated weight search makes learning in NNs somewhat more *autonomous* in that while the application is running, the weight search becomes independent of the programmer. Of course, it is not *completely* autonomous, as the programmer must still code the application but also for another, more specific reason.

The perceptron learning algorithm exemplifies the general definition of learning in NN modeling as a *change in one or more connection weights*. In this algorithm, learning thus defined occurs only when the perceptron *errs* (Steps 2b and 2c). Otherwise, the perceptron does not learn. Strictly, then, this algorithm only models learning by *failure*, not by success (Step 2a). In this sense, the perceptron learning rule is an *error-correction* rule and illustrates how erring *defines* a NN model, in sharp contrast to Turing’s characterization of his automatic machines as flawless.

This kind of learning is also known as *supervised* in that it implies an external.

“supervisor” or “teacher” that tells the system when it errs (in real teaching situations, the teacher would remain silent when the student succeeds). This implication obtains from the notion of a *desired* or *expected* output activation (as defined in the task), which prompts the question “Desired or expected by whom?” A natural answer is to assume an expectant agent that assists the perceptron in erring less frequently, another reason why this kind of learning is less autonomous (i.e., does not capture *autodidacticism*).

Minsky and Papert (1988) demonstrated that perceptrons with one input-unit layer and one output-unit layer could not learn tasks that were inseparable by a *hyperplane* (a general term that includes tasks with *any* number of inputs, defined as a subspace with one less dimension than its Cartesian coordinate system). About 88% of the possible tasks for a perceptron with the MCP1 structure are separable by a hyperplane, which is not bad at all. However, the percentage of these tasks tends exponentially to zero with the number of inputs (for a perceptron with just 9 input units, the percentage is  $1.075 \times 10^{-135}$ ), a major limitation. Most TCS and TAI researchers of the time mistook this limitation as *inherent* to *all* NNs, making them reject the connectionism hypothesis, which bolstered TCS and TM AI to become the dominant approach to theorizing about the mental for over a decade.

## CCS Vindicated: Backpropagation

A few scholars continued working on the CCS hypothesis and made important advances, but its decisive resurgence came with the publication of the PDP (“parallel distributed processing”) volumes (McClelland et al. 1986). This publication proved early rejections of NN modeling premature. A major development was the discovery that perceptrons with a hidden layer could do tasks that were inseparable by two hyperplanes (see Fig. 5). Another key advance was the use of a *continuous* activation rule.

A widely used continuous activation rule is the *logistic function* (which has a sigmoid shape that

resembles a stretched S), often expressed in abridged form as

$$a_{j,t} = \frac{1}{1 + e^{-x_{j,t}}}, \quad (3)$$

where  $x_{j,t}$  is defined in Eq. 2 and  $e \approx 2.71828 \dots$  is the base of natural logarithms. Its continuous character makes this function *differentiable*, meaning that it allows for the definition of a *derivative*, a fundamental concept in *calculus* (another part of mathematics that has been central to NN modeling). The derivative of a function is an equation to calculate the *slope* of a straight line that is *tangent* to the function at one of the function’s points. (The slope is a measure of how fast the function is/was changing at that point.)

By far, the most popular use of this concept in NN modeling is *backpropagation* (e.g.), in an error-correction learning algorithm known as *gradient descent*, which basically seeks to reduce a NN’s error, as part of this learning rule:

$$\Delta w_{i,j,t} = \alpha \delta_{j,t} a_{i,t}, \quad (4)$$

where  $\Delta w_{i,j,t}$  denotes the change ( $\Delta$ ) in the weight ( $w$ ) of the connection from  $i$  (an input or afferent) to  $j$  at  $t$ ,  $\alpha$  denotes the learning rate (a free parameter that influences how much  $w_{i,j,t}$  changes), and  $a_{i,t}$  denotes the *actual* activation state of  $i$  at  $t$  (computed according to Eq. 3, if  $i$  is a hidden unit connected to output unit  $j$ ).

The key term is  $\delta_{j,t}$ , the specific quantitative contribution of  $j$ ’s activation to an error at  $t$  in a feedforward NN with one hidden layer (e.g., upper middle panel of Fig. 1). Technically,  $\delta_{j,t}$  is the *partial* derivative of Eq. 3 with respect to  $x_{j,t}$ , computed differently for hidden and output units, *after* the *forward-propagation* phase (computation of the *actual* activations of *all* hidden and output units for a given input pattern at  $t$ , according to Eq. 3). If  $j$  is an output unit,  $\delta_{j,t}$  crucially includes a *prediction error* defined as  $a_{j,t} - d_{j,t}$ , where  $a_{j,t}$  denotes  $j$ ’s *actual* activation (computed according to Eq. 3) and  $d_{j,t}$  denotes  $j$ ’s *desired* activation for the current input pattern, as stipulated by the task. Once computed,  $\delta_{j,t}$  is sent *back* (hence the name “backpropagation”) to the

hidden units connected to  $j$  and used to compute  $\delta_{j,t}$  for them and change the corresponding weights. In general, the greater the value of  $\delta_{j,t}$ , the greater the weight change, everything else being equal.

## Concluding Remarks

Thanks to these and other developments, NN modeling has become dominant in cognitive science and AI tech research. This research has overcome the obsession TCS and TAI researchers have for the TT, moving beyond an anthropocentric and symbolic-centric view of the mental. All this has made for a more inclusive cognitive science that contemplates the possibility of non-symbolic cognition, human and nonhuman.

The foundations summarized above have had a strong engineering import, but they also inform scientific understanding of natural minds, although not without important modifications. For example, the view of learning as error correction has been very influential in computational modeling of *Pavlovian conditioning*, the simplest form of associative learning studied in animals (see ► “[Learning](#)” entry in this encyclopedia). According to a standard NN interpretation (e.g., Sutton and Barto 1981), error correction is at the core of the most influential model of Pavlovian conditioning, proposed by Rescorla and Wagner (1972). However, these interpretations do not include the kind of mechanism found in the back-propagation model.

I have only skimmed the surface of NN modeling, focusing on the fundamentals of supervised learning in feedforward NNs. As anticipated in the first section, there are other types of NNs and learning algorithms. Unfortunately, I can only mention a few very briefly, without doing them the justice they deserve.

In one important category of NN models, learning is *unsupervised*, which does not occur by error correction. As the name suggests, this kind of NN learning does not imply the presence of a teacher. Rather, weights change depending on the levels of co-activation of the connected units. In this sense, unsupervised learning is somewhat

more autonomous. A paradigmatic example is Hebbian learning (after Hebb 1949). In its simplest form, Hebbian learning occurs according to this rule (Hebb did not formulate it computationally):  $\Delta w_{i,j,t} = \alpha a_{i,t} a_{j,t}$ , where  $a_{i,t}$  denotes  $i$ 's (an afferent's) activation state at  $t$  and  $a_{j,t}$  denotes  $j$ 's activation state at  $t$ . Other unsupervised-learning NN models include the *self-organizing map* introduced by Kohonen (2001) and the *adaptive resonance theory* (e.g., Grossberg 2013).

Yet another category of NN models involves *reinforcement learning*. In their version, Sutton and Barto (2018) have drawn from experimental animal research on conditioning. They conceive Pavlovian conditioning as learning to *predict* that a certain biologically significant stimulus reliably follows a biologically nonsignificant cue. They also try to account for operant or instrumental conditioning, a more complex form of associative learning where animals are rewarded for acting in certain ways on their environment (see ► “[Learning](#)” entry in this encyclopedia), conceiving it as learning to *control* the environment through actions that have consequences. Recent NN models of conditioning have tended to maintain a sharp distinction between Pavlovian and operant learning algorithms. One exception is the model proposed by Donahoe et al. (1993), which seeks a more unified approach by using the *same* learning algorithm to simulate *both* kinds of conditioning. This model makes no distinction between operant and Pavlovian *learning*.

In sum, the pursuit of the CCS hypothesis through NN modeling has changed cognitive science significantly, and its AI tech achievements have been very impressive. At least some, perhaps most of it has been for the better, and the overall balance seems positive, but it still is too soon to know where it will lead. Only future research can tell. Meanwhile, the field will benefit from heeding a lesson from past research: avoid premature overenthusiasm. Enthusiasm motivates and inspires, but it is wise to keep it in check. Beware of the recent hype about CAI, especially machine and deep learning AI.

It thus is wiser to pursue CCS as a *working hypothesis* very much in need of further investigation. Despite significant progress, Smolensky's

(1988) assessment that “the connectionist approach is still quite underdeveloped” (p. 2) remains valid. Further progress requires continued discussion of the approach’s difficulties. Some are practical and more relevant to CAI tech research. Here I focus on a potentially more worrisome problem from a basic-scientific modeling perspective: it is very difficult to *explain thoroughly and intelligibly* why particular NNs function the way they do in specific tasks. CAI tech researchers too face this problem but care more about NNs doing their job effectively and efficiently than explaining why.

I gave a glimpse of the problem in the third section. There, I suggested that it would be impractical to explain thoroughly why a particular MCP NN with just three input units connected to one output unit *succeeds* at a particular task, *if* this explanation was a mathematical demonstration of the solvability of the corresponding system of linear Boolean inequalities. The perceptron learning algorithm makes this demonstration unnecessary, because it allows for an automated search of a solution with a computer. There also is the perceptron *convergence theorem*, a mathematical proof that the perceptron learning algorithm will find in finite time a solution for any *solvable* system.

However, it is not obvious exactly how all this would make a thorough explanation more intelligible or even viable. Much depends on the explanation’s form and the perceptron’s size as determined by the task. It would seem viable to explain thoroughly why a perceptron with three input units connected to one output unit succeeded at a particular task through a computer simulation that preserves the eight final weights. This explanation could show the eight final connection weights and appeal to the convergence theorem to assert that they solve the task’s system of linear Boolean inequalities, but how *intelligible* would this be? To begin with, understanding the theorem’s *proof* would seem necessary to understand the explanation, but this is not easy, especially for the non-expert. How intelligible or even viable would be a thorough explanation of why such a perceptron *failed* a particular task?

The problem arises from NN size *with unrealistic, simplified activation and learning functions* like

the perceptron’s. Therefore, simplifying them does not ease the problem. The search for realism in computational neuroscience also promotes the use of NNs too large for thorough explanations to be intelligible or even viable. A realistic NN of the *C. elegans* brain, one of the simplest known to neuroscience, would consist of about 300 units and 7,000 connections. It is far from obvious how intelligible or even viable would be a thorough explanation of why such a NN functions in particular situations. The search for realistic activation and learning functions only exacerbates the problem.

In general, then, NN model realism decreases the viability and intelligibility of explanations of why particular NNs function the way they do in particular situations. The problem is not exclusive to NN modeling but afflicts *all* computational modeling of complex phenomena that seeks realism nor is the problem new; it arose decades ago under the name of “Bonini’s paradox” (see Dawson 2004, pp. 17–18, 121–125), in reference to computer simulations that are as difficult to understand as the simulated phenomena are.

Avoiding this problem is necessary for progress in NN modeling, but particular ways vary across models and phenomena. The root of the problem is that two key virtues of explanations, parsimony and realism, relate inversely. The only options, then, are either to maintain realism and reduce explanation intelligibility or vice versa. The wisest strategy for the time being is to seek a judicious *balance*. Unfortunately, it remains unclear where such balance is, let alone how to achieve it.

## Neuroanatomical Plasticity

Kelly Stewart  
Hofstra University, New York, NY, USA

## Synonyms

Structural plasticity

## Definition

The ability of the brain to physically change and reorganize itself in response to learning and experience.

## Introduction

For many years, the idea that specific functions and behaviors were hard-wired and localized to one specific brain region was dogmatic throughout the scientific community. However, a shift away from the Doctrine of Localization was observed in the 1970s and 1980s when acknowledgement of the brain's ability for change as a result of experience first gained popularity. Since then, the development of modern technology has provided scientists with the tools to back up the speculation that behavioral changes are correlated with neuroanatomical changes with evidence at the structural level. Now, acceptance of the brain's ability to reorganize itself in response to stimulation, novel information, development, and damage has swept the neuroscience community and lead to the acceptance of neuroplasticity as a fundamental function of the nervous system.

## Neurobiology of Structural Plasticity

The overall ability of the brain to change is primarily a result of activity that occurs at synapses (the connections between neurons). There are two primary types of changes that can occur at the synapse. The first involves the formation of novel neuronal connections and is known as Synaptogenesis. The process of synaptogenesis is believed to begin when the dendritic spines (projections off of the cell body of a neuron) of one neuron reach out to the axons of nearby neurons and actively pull them closer to the cell body (McCallister 2000). Once the initial recruitment of nearby axons to dendrites has occurred, the solidifying of the neuronal connections is dependent upon neurochemical communication between the pre-synaptic neuron (axon) and the post-synaptic neuron (dendrite).

Once neurons are brought together and synapses are formed, the strength of the connection is subject to change as a direct result of activity. This phenomenon, known as Synaptic Plasticity, is the second type of change that can occur at the synaptic level and generally functions in line with the commonly known principal of “use-it-or-lose-it.” Each time that a neuron is stimulated, or “used,” by a pre-synaptic neuron, a strengthening in the connection between the two neurons is observed. In other words, repeated stimulation by a pre-synaptic neuron leads to the strengthening in response of a post-synaptic neuron resulting in the Long-Term Potentiation (LTP) of the connection between the two neurons.

On the flip side of this is a phenomenon known as Long-Term Depression (LTD). LTD is observed when a decrease in stimulation by a pre-synaptic neuron leads to a decrease in response of a post-synaptic neuron. This decrease in stimulation eventually causes the connection between the two neurons to be “lost.” Taken together, LTP and LTD make up the mechanism by which the brain is able to achieve cortical map reorganization.

Beyond changes at the synapse, the brain is also capable of changing through the formation of new neurons – Neurogenesis – and the eradication of existing neurons. The greatest rate of neurogenesis occurs in the womb and throughout development. However, neurogenesis can also occur into adult hood and be stimulated by hormones released after the brain experiences trauma (Wieloch and Nicolich 2006).

## When Does Neuroanatomical Plasticity Occur?

Plasticity is not just something the brain is capable of; plasticity is the constant state of the brain. From the onset of neuronal development to death, the brain persistently demonstrates its unparalleled plastic abilities. From the perinatal onset of neuronal development, the brain gains neurons at a rate of about 250,000 nerve cells per minute. At the time of birth, neurons in the cerebral cortex of the human brain form roughly

7000 connections each and, though the rate has decreased from that of perinatal development, nerve cells are still being added (Ackerman 1992). By the age of seven, the number of connections for each neuron increases to about 15,000. Following this rapid state of expansion in the brain, an event known as Synaptic Pruning occurs where the principles of “use-it-or-lose-it” are put into place and the synaptic connections that are being used are strengthened and the ones that are not are broken. At the end of this developmental process each neuron has somewhere between seven or eight thousand connections.

Though neurogenesis does greatly slowdown after the developmental stage, plasticity in the brain persists. Every time something new is learned or forgotten – be it a skill, a person, a task, a motor function, or anything else – the brain is capitalizing on its plastic abilities.

Another time where the brains plasticity is strongly capitalized on is following brain trauma. Often times, trauma to the brain can result in the loss of the function for which the damaged brain region was responsible. However, thanks to both functional and structural plasticity, the recovery of the lost behavioral function is possible. Following damage, the brain may structurally alter its neural maps and connections by temporarily entering into a state of neurogenesis as well as increasing the the connections between healthy – or undamaged – brain regions to compensate for or take over the role of the lost function.

## Definition

Neurogenesis is a process of generation of functional neurons from the precursors, which happen during the embryonic and prenatal stage in mammals.

## Introduction

Neurogenesis is a process where neurons are generated from precursors (neural stem cells and progenitor cells). Neurogenesis comes from two terms, neuro or nerve cells and genesis means creation or beginning of, combined it simply is the creation of new nerve cells. Adult neurogenesis is a process where new neurons are born after postnatal stage from adult neural precursors. A typical neuron generation takes place in three distinct stages, cell proliferation, cell migration, and cell differentiation.

## Neurogenesis

Neurogenesis is the most important phenomena during the embryonic development of any species. The main reason for this is that to develop a functional connection between neurons requires the generation of specific neuron types, and their correct migration and differentiation at the precise time in the development stage. During embryonic neurodevelopment, an embryo has three distinct layers (endoderm, mesoderm, and ectoderm), which give rise different part of the body. Ectodermal layer forms the nervous system and skin.

Neuron production in human begins on embryonic day 42 or E42, and differentiation of neural progenitor cells extends to late adolescence. These neurons migrate to different brain parts and begin making connections to form the primary neural networks. After the gastrulation period of embryo, neural stem cells emerge and they are capable of producing all different type of cells that are required in the central nervous system. Neural stem cells are also called neural progenitor cells. After formation of these progenitor cells, these cells are positioned along the upper layer (ectoderm) of the embryo and this region is called neural plate.

Next important step in development is formation of neural tube which forms along the two sides of the neural plate and later becomes a hollow tube and eventually forms the ventricular system of the brain. Neural progenitors are located in a region of the brain called ventricular zone (VZ) (Stiles and Jernigan 2010). At E42 stage neural progenitors go through asymmetrical cell division and give rise to one stem cell and one neuronal precursor cell (neuroblast) that never go for cell division again (Purves et al. 2004). Neuroblasts once exiting cell cycle leave the proliferative VZ to further differentiate into neurons and other specific cell types and subsequently migrate to target areas in the brain. These neuroblasts give rise to several neuronal cell types depending on brain area they are targeted and type of connections they will form. Neuronal differentiation is based on local cell-cell interaction and several transcription factors expressed in each cell.

Migration of postmitotic neuroblasts brings together the different class of neurons together

for dynamic interaction and development precise connection at the synaptic level. Some neuron migrates shorter distance whereas neurons that migrate greater distance require a special type of cells called “radial glial cells” to act as a guidance system. Neurons that leave the VZ earlier forms the deepest layer of cortex and later neurons make the superficial layers. This order of migration is termed as inside-out (Stiles and Jernigan 2010). After reaching at target location in cortex and elsewhere in brain, these neurons need to form connections and makeup the rudimentary neural network. In order to do so, they develop neuronal processes (axon and dendrites) with help of some signaling molecules that allow them to communicate with other neurons (Fig. 1).

Until last two decades, it was in consensus that once the brain has developed and neurons have settled in various networks, it is impossible to generate new neurons and adult neurogenesis does not occur. But this was challenged by few scientists who observed that few part of the brain still undergo neurogenesis in the adult state of the brain also, two discrete regions of the brain were identified, dentate gyrus of the hippocampal formation and subventricular zone (SVZ) and its projection to the olfactory bulb (Gage 2002). This new discovery was very important for two main reasons: first is that brain is capable of much more plasticity than previously thought, and second in the case of brain trauma, there are higher chances of brain repair now using stem cells from these regions.

## Conclusion

Neurogenesis is a critical part of brain development structurally and functionally. This development process requires availability and appearance of these neurons at the right time, which is ensured by the various stages of neurogenesis. Migration and differentiation of neural progenitor cells ensure this process goes smoothly. Adult neurogenesis, the amazing phenomena of the brain to generate new neurons in adulthood has opened doors to many opportunities to mitigate the brain degenerative processes in various disease

conditions. New therapeutic treatments are available now and continue to develop using adult neural stem cells and promise a new dimension in disease treatment.

## Definition

A neuron is a specialized cell that transmits electrical impulses and is the basic unit of the nervous system.

## Introduction

Neurons are the basic unit of the nervous system; when bundled together they create nerves, the spinal cord, and the brain. They can transmit information with electrical and chemical signals. This characteristic allows for processing in different brain structures and for sending information throughout the body. To do this, neurons form networks and communicate with each other via nerve impulses, also known as action potentials. Typically, a neuron has dendrites to receive electrical signals, a cell body, or soma, for integration, an axon for propagation, and axon terminals to release neurotransmitters into the synaptic cleft, a junction between two neurons.

All neurons have a relative negative resting potential that is maintained by the sodium-potassium pump. There are three major ions in the electrochemical activity of a neuron: potassium, sodium, and calcium. The concentration of potassium is higher inside the cell than outside, while the concentrations of sodium and calcium

## Neuron

Nerve cell

are higher on the outside than inside. The electrical activity caused by a stimulus will affect the permeability of a neuron causing these ions to change the cell's resting potential, allowing for the transmission of information. The aggregate activity of neuron action potentials accounts for nearly all the activity of the nervous system.

To create complex networks and circuits, there are different types of neurons within the nervous system, each varying in structure, function, and location. Some differ in their direction of firing, sending information from the peripheral nervous system (PNS) to the central nervous system (CNS), or vice versa. Neurons also have different structures that are driven by polarity, the projections that extend from the cell body. Lastly, there are neurons that, when fired, release primarily one neurotransmitter. These neurons are present in certain neuronal pathways that often have a specialized function, like dopamine pathways for controlling movement and reward.

### Neurogenesis and Maintenance

Unlike most cells in the human body, neurons do not undergo cell division and their formation

typically stops at adulthood. Neurons are developed and maintained with support from differentiated cells, such as glial cells, and substances such as neurotrophins (Palmer et al. 1999). Neurotrophins are a class of growth factor that play an important role in the generation and overall health of new and existing neurons, both in newborn and adult animals. Neurotrophins interact with signaling pathways involved in the generation, maintenance, and differentiation of neurons (Takahashi et al. 1999).

### Structure and Function of a Neuron

A neuron is composed of dendrites, a cell body, an axon, and axon terminals (Fig. 1a). The dendrites contain receptors that bind to specific neurotransmitters released from the presynaptic neuron. Usually, this area is the starting point for an action potential. An important aspect of dendrites is their widespread layout and density, increasing their ability to synapse with many other neurons and brain regions (Lodish et al. 2000b). This property is known as arborization. Dendrites with greater arborization feature larger dendritic fields. To further increase neuronal connectivity, dendrites

**Neuron, Fig. 1** Structure of a neuron. (a) General structure of multipolar neuron containing dendrites, a cell body or soma with a nucleus, the axon hillock, axon, myelin,

nodes of Ranvier, and axon terminals. (b) Close-up of dendrite showing structure of dendritic spines. Image is not to scale

contain spines that receive most of the incoming excitatory signals (Kasai et al. 2003). Each of these spines represents another synapsing point. A dendritic spine is made up of a head and neck, with the former featuring a postsynaptic density (PSD) (Fig. 1b). The PSD is an area that contains many receptors and proteins that facilitate neural transmissions through increased neurotransmitter binding. Spines are highly plastic and react to the amount of input they receive. Maturation and increased cognitive processing, such as learning, can lead to well-developed dendritic spines, while diseases and lack of stimulation can weaken or destroy them (Wong and Ghosh 2002).

The cell body contains the nucleus, with all genetic information, and other life-sustaining organelles, such as the mitochondria, endoplasmic reticulum, ribosomes, and Golgi. The main function of this structure is to provide all necessary materials for the cell, such as proteins. The cell body also receives electrical signals from the dendrites and integrates them at the axon hillock, or initial segment. If the signal is strong enough, it is transmitted to the axon (Lodish et al. 2000b).

Attached to the cell body is a long projection called the axon. Once an action potential is initiated, it is conducted down this structure, away from the cell body. The axon contains many voltage-gated ion channels, mainly calcium and potassium, that are involved in an action potential (Lodish et al. 2000b). The axon is sometimes insulated by myelin to protect the signal from degrading and slowing down. Schwann cells and oligodendrocytes are two types of cells that produce myelin, with the former working in the PNS and the latter working in the CNS. Myelin does not completely cover the axon, instead only covering segments. Gaps in these segments are called nodes of Ranvier. These nodes allow for faster propagation by a process called saltatory conduction, in which a signal can pass quickly through the myelin, jumping from node to node. The axon diameter also plays a factor in the velocity of an action potential. As the axon diameter increases, so does the velocity of the action potential (Salami et al. 2003).

The end of a neuron features axon terminals that usually synapse with dendritic spines. These terminals contain vesicles filled with

neurotransmitters. When an action potential reaches the terminals, the positive charge activates voltage-gated calcium ion channels. Calcium ions rush into the cell and bind to proteins that initiate a series of events in which the vesicles fuse with the membrane to release the neurotransmitters. Presynaptic neurons can also repackage neurotransmitters in the cleft to be reused. The synapse marks the end of an action potential and the transmission of information (Lodish et al. 2000a).

## Types of Neurons

Neurons can be characterized by structure, such as polarity, and by function, such as firing direction or neurotransmitter production. Polarity refers to differences in the structural development of a neuron and is subdivided into categories: unipolar, pseudounipolar, bipolar, multipolar, and anaxonic. A unipolar neuron has only one projection from the cell body that splits into two axons, featuring dendrites and terminals at opposite ends (Fig. 2a). This type of neuron is primarily found in invertebrates and is used for touch and pressure sensation. Pseudounipolar neurons are similar to unipolar neurons in structure and function (Fig. 2a). However, they develop from a bipolar cell and are found primarily in vertebrates. In humans, the pseudounipolar neuron branches from the sensory organ to the spinal cord. Bipolar neurons have two projections extending from the cell body, one for dendrites and the other for terminals (Fig. 2b). These neurons are found exclusively in the olfactory bulb and retina. Multipolar neurons have a single process and numerous dendrites that project from the cell body (Fig. 2c). They are the most common type and makeup the bulk of neurons in the brain (Squire et al. 2008). An anaxonic neuron is one in which the axon is short and therefore cannot be differentiated from the dendrites or terminals (Fig. 2d). These neurons mainly work to integrate signals from many neurons and can be found in the retina and parts of the brain, like the olfactory bulb (Crespo et al. 2013).

Another way to characterize a neuron is by the direction of firing. A neuron that sends information from the CNS to organs and limbs is called an

**Neuron, Fig. 2** Structural differences of neurons dictated by polarity. (a) Structure of a unipolar or pseudounipolar cell with a single projection from the soma. (b) Structure of a bipolar cell with dual projections from the soma. (c)

Structure of a multipolar cell with a single projection from the soma. (d) Structure of an anionic cell with unidentifiable axon

effluent neuron. Motor neurons allow for movement, as they send signals from the brain to the PNS to control processes like muscle contraction and gland secretion. Conversely, a neuron that sends information from the sensory organs to the CNS is called an afferent neuron. Sensory neurons are those that respond to the environment. They gather information from sensory receptors and send it to the brain to be interpreted. Linking the sensory and motor neurons with the CNS are interneurons, which can be afferent or efferent. These neurons also serve as connections between brain structures, creating circuits, and are only found within the CNS (Squire et al. 2008).

Neurons can also be classified by their production of neurotransmitters and the effects on postsynaptic neurons. There are two main classes of neurotransmitters, excitatory and inhibitory. Excitatory neurotransmitters increase the likelihood for an action potential to occur while inhibitory neurotransmitters do the opposite. There are five main neurotransmitter classifications of neurons that have receptors for Acetylcholine, GABA, Glutamate, Serotonin, and Dopamine.

Cholinergic neurons work with receptors that can be excitatory or inhibitory, and are present in learning and memory pathways. GABAergic neurons produce inhibitory effects, as they hyperpolarize postsynaptic neurons. Glutamatergic neurons work with four types of receptors that produce excitatory effects in postsynaptic neurons, facilitating neural transmission. Serotonergic neurons can be excitatory or inhibitory, and play important roles in sleep, mood, sexual behavior, and anxiety. Lastly, dopaminergic neurons may be excitatory or inhibitory, depending on the neural pathway. Most commonly, dopaminergic neurons are implicated in movement and reward pathways (Lodish et al. 2000a).

## Circuits

Circuits are collections of interneurons that cluster in groups and form ensembles, which connect in series with others around the brain. These circuits carry electrical signals through brain structures and serve specific functions, from basic sensation

processing, like vision, to more complex processing, like emotions. Myelin is especially important in these circuits, as it allows for increased conduction velocity throughout distant brain structures (Salami et al. 2003). Destruction of these myelinated pathways, and the subsequent increase in transmission timing, can deteriorate healthy brain function and result in many neurodegenerative ailments, such as multiple sclerosis (Lodish et al. 2000b).

## Definition

Neurotransmitters are chemical messengers in the brain that transmit a signals from one neuron (nerve cell) to another neuron, muscle cell, or gland cell (Lodish et al. 2000).

## Synaptic Space and Neurotransmitter Mechanism

The synaptic space consists of three functional parts: the presynaptic membrane, the synaptic cleft, and the postsynaptic membrane. These highly specialized membranes ensure that vesicles containing neurotransmitters are released at its appropriate active sites (Patestas and Gartner 2016). Neurotransmitters are composed of amino acids, the basic building blocks of proteins. Neurotransmitters are stored and released from synaptic vesicles, which are found at the terminal end of a neuronal axon (Ikeda and Bekkers 2009). A neuronal signal is conducted after an action potential has been initiated by releasing neurotransmitters into the synaptic space, a microscopic gap that exists where the axon of one neuron meets the dendrite of another. During depolarization of the action potential, the synaptic vesicles will fuse with the presynaptic membrane (Purves et al. 2012). The influx of calcium from depolarization will cause the synaptic vesicle to attach to the presynaptic membrane allowing the neurotransmitters to release (Patestas and Gartner 2016). The neurotransmitters attach to corresponding receptors at the receiving neural, muscle, or gland cell (Thompson 2000). A released neurotransmitter exists in the synaptic space for a short period of time before it is either bound to a receptor or metabolized by enzymes. Neurotransmitters may influence neurons in an inhibitory or excitatory manner (Sapolsky 2005). They influence neurons by causing ion channels to either open or close in order to depolarize or hyperpolarize the target cell membrane (Patestas and Gartner 2016).

## Types of Neurotransmitters

Neurotransmitters must meet the following main criteria (Patestas and Gartner 2016):

1. Neurotransmitters must be present or synthesized within a neuron.
2. Neurotransmitters must be stored in synaptic vesicles.

3. Upon neural activation, the neurotransmitter must produce a response at the target cell receptor site.
4. An identical response must be produced when the neurotransmitter is experimentally placed at the target cell receptor site.
5. A removal mechanism must be intact to remove the neurotransmitter from its activation site after its release from the neuron.

The term “neurotransmitter” can also be used to define chemicals that:

1. Carry messages between neurons
2. May or may not have an effect on membrane voltage, but can change the synaptic structure
3. Communicate messages that affect the release or reuptake of other transmitters (Breedlove et al. 2013).

## Classification of Neurotransmitters

Neurotransmitters are classified into biogenic amines, neuropeptides, and small molecule neurotransmitters.

### Biogenic Amines

Biogenic amines are neurotransmitters made from amino acids, the building block of proteins. Norepinephrine, epinephrine, dopamine, serotonin, and histamine all fall under the biogenic amine category. These neurotransmitters are quickly digested after release and therefore are only responsible for a limited number of depolarizations or hyperpolarizations (Patestas and Gartner 2016).

### Neuropeptides

Neuropeptides are small neuronal proteins that are used by neurons to communicate with each other. They tend to be co-released during an action potential in order to enhance or inhibit the effect of other neurotransmitters. Endorphins are an example of neuropeptides (Patestas and Gartner 2016).

### Small Molecule Neurotransmitters

Small molecule neurotransmitters are low molecular weight proteins synthesized in the presynaptic terminals. Some examples are acetylcholine, gamma aminobutyric acid (GABA), glycine, and glutamate.

### Neurotransmitter Imbalance and Disorders

There are no standardized levels for each neurotransmitter in the body due to the inability to accurately measure the concentration of each individual neurotransmitter at any given time; often times, various neurotransmitters regulate the concentration of other neurotransmitters further deeming it difficult to measure (Trofimova 2016). Neurotransmitters can provide significant effects on the brain in smaller amounts (Sapolsky 2005). A consistent imbalance of neurotransmitters is responsible for various disorders like depression, schizophrenia, attention deficit hyperactivity disorder, autism, and obsessive-compulsive disorder. Most psychoactive drugs affect neurotransmitter activity in order to treat psychological disorders (Sapolsky 2005).

## Synonyms

Force; Motion; Movement

## Introduction

Intuitively, a body's movement remains constant unless there is an external factor acting on it, which is called *force* (Halliday et al. 2012). In nature, it is observed that forces arise in pairs since for each existent force there's another with the same intensity but in the opposite direction. This phenomenon is known as *Newton's third law*. From this perspective, Newton's third law remarks that forces *always* arise in pairs. This can be verified in many different practical situations; as a person walks through a solid surface, for example, pressing their feet against the ground ( $F_1$ ), there's a so-called friction force ( $F_2$ ) propelling the person's body forward (Nussenzveig 2013; Taylor 2013) (Figure 1). For another example, in Figure 2, while an astronaut in the middle of space throws an object forward ( $F_1$ ), the same object will exert a force ( $F_2$ ) on the astronaut, launching him in the opposite direction.

## Animal Locomotion

Analogous to the astronaut walking on the moon or throwing an object into space, Newton's third law

also applies in the movement of animals: in the flight of a bird, the wings make a force pushing the air downwards, and the air reacts with an equal and opposite direction force, pushing the bird upwards; when a fish is swimming, it pushes the water backward, and the water reacts and pushes the fish forward. Even though there are intricacies to the nature of the force in any example that can be observed, Newton's third law concerns only with the overall concept of forces, their direction, and intensity.

## Remarks

The examples presented in the previous discussion assumes one important point about the interaction between objects: any other forces acting on them have negligible effects, and it's only considered their overall effect. In the example of a bird flying, the air currents propel nontrivial individual forces through the bird's body; notwithstanding, when taking all contributions, there'll be a resultant force responsible for the bird's flight. The same reasoning can be applied to the fish swimming through the water or any other physical phenomena that it's observed in everyday life.

Another significant aspect is that, in these examples, the interaction between the objects occurs with contact forces; this means that the time of interaction between them is really small and the forces can be understood as instantaneous – the time interval between the force of the astronaut's feet against the lunar soil and the force propelling the astronaut forward is effectively imperceptible, for example. It's from this “instantaneous interaction” perspective that arises the idea that the forces always arise in pairs (Halliday et al. 2012). It's also important to remark that Newton's third law shouldn't be confused with the “action-reaction” erroneous perception of the influence of a posterior event due to initial and small conditions. An illustration of this is the famous metaphorical example of the “butterfly effect,” where the formation of a tornado could be influenced by the flapping of a butterfly's wings. The idea here is not to take this example literally but to illustrate that there are systems that are sensitive to small changes on the initial conditions and they have nothing to do with Newton's third law.

## Niche Divergence

Abhishek Singh  
Department of Botany, Banaras Hindu University,  
Varanasi, India

### Definition

Any change in ecological niche (fundamental and realized niche) due to abiotic (climatic) and biotic (e.g., competition, predation, parasitism, etc.) constrains on a subgroup of population, and

subsequent adaptation to this diverge niche is known as niche divergence.

## Introduction

The organisms tend to live and reproduce in a given set of environmental conditions, known as niche. Various abiotic and biotic factors determine the limit of occurrence range of a species. The niche can be further divided into realized and fundamental niche. Fundamental niche can be defined as the range of environmental (abiotic) conditions under which population of a species can survive and maintain a positive growth rate. The potential niche is the subsection of fundamental niche, which allows a species to survive and reproduce at specific point in time. The realized niche is a subsection of potential niche which is actually occupied by population of a species despite the biotic interactions like competition, predation, etc. (Hutchinson 1957; Jackson and Overpeck 2000). However, the environmental conditions are not always constant; the ever-changing interaction among populations and its abiotic and biotic components influence its growth and occurrence. These factors influence the behavior of organisms, which leads to change in their fundamental, potential, or realized niches. These changes in ecological niches lead to speciation by natural selection.

Evolutionary ecologists suggest that mutation-order and ecological speciation are the two marked mechanisms for speciation by natural selection. The mutation-order speciation involves the fixation of advantageous/neutral mutations among a subgroup of the population, which leads to increase in the frequency followed by genetic isolation in same ecological niche. On the contrary, ecological speciation occurs through the appearance of different environmental conditions within an ecological niche and adaptation of a subgroup of the population toward it followed by niche divergence, which ultimately leads to genetic isolation and speciation (Fig. 1). Mutation-order speciation is based on the principle of niche conservatism, while ecological speciation relies on the niche divergence. Both niche

**Niche Divergence, Fig. 1 Ecological speciation through niche divergence:** The abiotic and biotic factors exert pressure on existing population due to which new ecological conditions generated within the existing niche.

Some individuals of population are adapted to these new ecological conditions and in turn give rise a new niche accompanied by niche divergence followed by genetic isolation and speciation

divergence and niche conservatism plays crucial role in ecological speciation. The niche divergence refers to the any change in ecological niche of a population of a species due to abiotic and biotic factors including climate, inter- and intraspecific competition, and constrain in food resources which ultimately leads to speciation (Rato et al. 2015). On the other hand, niche conservatism is the conservation of ecological niche in due course of time by a population of a species which also leads to speciation (Wiens 2004).

## Causes of Niche Divergence

**Climate:** Climate is a key component in determining the ecological niche of species. As the organisms are well adapted to their habitat, any change in prevailing climatic conditions affects their normal behavior. The climatic conditions such as temperature, precipitation, and solar radiation are directly associated with the feeding and mating habit of organisms. All the terrestrial organisms have tendency to live in a set of climatic conditions (temperature and precipitation), known as climatic niche (Holt 2009). The climatic niche is crucial for determining the occurrence of a species in an ecosystem along with other abiotic and biotic factors and its response to the climatic changes at temporal and spatial scale. Every species has a range of climatic conditions

where it occurs, known as climatic niche width (e.g., maximum and minimum annual temperature and annual precipitation across a geographical area). However, the climatic variables may differ from one locality to another within a geographical area; this will lead to the adaptation of subgroup of a population to their corresponding climatic condition, which further leads to divergence of niche and genetic diversification from original population (Hua and Wiens (2013).

**Biotic interaction:** Biotic interactions such as inter- and intraspecific competition are major determinants of ecological niche of a species (realized niche). Interspecific competitions such as predation and parasitism have greater impact on niche occupied by the organisms. Predation and parasitism exert pressure on existing subgroup of a population, which results in niche divergence. The intraspecific competitions are fiercer among the population of a species as they compete for same resources. This will force the subgroup of population to change their habit to avoid competition and consequently gives rise to new niche characteristics which differs from the original and help the group of individuals to survive.

In natural ecosystems climatic and biotic factors work in combination to exert differential evolutionary responses and motifs of climatic tolerances which eventually leads to adaptation of populations in new habitats (niche divergence).

## Role of Niche Divergence in Speciation

Niche divergence plays key role in ecological speciation. The deviation from geographical range position and extent among species is caused by niche divergence. Due to differences in geographic range, the subgroups of population experience different environmental condition leading to niche divergence. The subgroup of population adapts to new environmental condition, which further leads to genetic/reproductive isolation and speciation through natural selection (Wiens and Graham 2005). Similarly, niche divergence due to inter- and intraspecific competition among species leads to speciation as the competing species tends to occupy different niches. This will lead to character displacement followed by natural selection and consequently speciation.

## Conclusion

Niche divergence is any displacement in niche characteristics due to abiotic and biotic interactions and consequently adaptation of group of individuals to this divergent niche. It is caused by several abiotic and biotic factors. In most of the cases, niche divergence caused by climatic factors is the main determinant of ecological niche. However, the biotic interactions are also an important factor contributing to niche divergence. Niche divergence caused by abiotic and biotic interactions leads to genetic and reproductive isolation of group of individuals in a population and in term speciation. Thus, niche divergence is a key driver to evolution and it plays key role in speciation.

## Nicola Clayton

Nicola S. Clayton

Comparative Cognition Laboratory, Department of Psychology, University of Cambridge, Cambridge, UK

## The Biography of Professor Nicola Clayton FRS

Known synonymously as The Bird Lady and The Dancing Professor, Nicky's work focuses on the behaviors and cognitive abilities of birds. Indeed it is her passion for birds that led to the development of her career as a scientist and her work in dance. Currently Nicky is the Professor of Comparative Cognition in the Department of Psychology at the University of Cambridge and a Fellow

of Clare College, Cambridge. She is also the first ever scientist in residence at Rambert, Britain's flagship touring dance company, a position she has held since 2011, and cofounder of *The Captured Thought*, a science-arts collaboration which explores the subjective experience of thinking, together with her tango partner, Clive Wilkins, who is artist in residence in the Department of Psychology at the University of Cambridge.

### Career History

Nicky spent her youth dancing and bird watching in and around Blackpool, a seaside town in the North of England, before going on to read zoology at Pembroke College, University of Oxford, from 1981 to 1984. This is where she met Lord John Krebs FRS, who was to become a highly influential figure in her scientific development. When applying to Oxford, she wondered whether to read zoology or PPP (Psychology, Physiology, and Philosophy). The clincher was when John Krebs explained that if she were to choose zoology, she could do research on birds at the Edward Grey Institute for Field Ornithology. Indeed her undergraduate research project investigated the role of memory interference in the food-caching habits of marsh tits – a species of titmouse that loves to live where the elm trees grow and obsessively hide food throughout the autumn and winter months and have long-lasting and highly accurate memories of where they have stashed their scattered stores of food.

For her PhD, Nicky went to St. Andrews University in Scotland to study how zebra finches and Bengalese finches learn their songs, focusing on the cues the birds use to decide which tutor(s) to copy, under the supervision of Professor Peter Slater, completing her PhD in just two and a half years. From there, Nicky went to the University of Bielefeld as a Royal Society postdoctoral fellow and was also awarded an Alexander von Humboldt-Stiftung to work with Professor Klaus Immelmann but sadly he passed away briefly before she arrived. Although she had no official mentor, Professor Joachim Bischof took her under his wing, and she very much felt part of his

wonderful academic family. She returned to Oxford to work with John Krebs on what was then called a Science and Engineering Research Council postdoctoral fellowship, before becoming the Department of Zoology's departmental demonstrator (akin to a temporary university lectureship) at Oxford University and taking up a Junior Research Fellowship at Linacre College coupled with a University Research Fellowship with the Agricultural and Food Research Council.

In 1995, she moved to California to take up an assistant professorship at the University of California Davis and rapidly rose through the ranks in the 5 years she was there – first as associate professor then full professor and Chair of the Animal Behaviour Graduate Group. It was a very special time – for that is when she met Dr. Nathan Emery, not only her key collaborator but also now her husband (since 2001). They share the same birthday (but not the same year), and arguably their most influential paper was published in *Nature* on Nathan's 30th birthday.

In 2000, she returned to the UK to take up a lectureship with tenure in the Department of Psychology at the University of Cambridge. In 2002, she was appointed a Reader, and in 2005, she was appointed to her current post as the Professor of Comparative Cognition. She was elected a Fellow of the Royal Society in 2010.

Her science-arts collaborations began in 2009 when she started to collaborate with Mark Baldwin, world-renowned choreographer and Artistic Director of what was then known as the Rambert Dance Company (formerly Ballet Rambert, and now Rambert), on *Comedy of Change*, a new choreographic work in honor of Charles Darwin's bicentenary and the 150th anniversary of "*On The Origin Of The Species*." She was appointed scientific advisor to Rambert the same year and the scientist in residence in 2011. One year later, she (together with Clive Wilkins) cofounded *The Captured Thought*, which explores the subjective experience of memory, perception, and consciousness by integrating science and the arts using their skills in tango and the performing arts. They have lectured, performed, and delivered workshops all over the globe – in science and arts venues alike.

## Research Contributions

Nicky's research in learning, memory, and cognition in birds has focused on three behaviors: bird-song, food caching, and food sharing.

Her first series of published endeavors for her PhD and initial postdoc focused on how estrildid grass finches, such as zebra finches and Bengalese finches, learn their songs and what the implications of this song tutor choice (Clayton 1987) was on sexual imprinting and mate choice (Clayton 1989). She then applied this way of thinking about behavioral development in birds to a new behavioral paradigm, food caching, to study how birds that rely on memory to hide food for the future develop these skills in hiding food and the effect this experience has on the development of both memory and the hippocampus (Clayton and Krebs 1994) and how this might not only be relevant to spatial memory but also the ability to episodically recall what happened where and when, an ability that had been previously assumed to be unique to humans (Clayton and Dickinson 1998). This finding led to the idea that these food-caching birds might also remember social aspects of caching, such as who was watching when they cached, and if so, whether they would be able to adjust their caching tactics accordingly to protect their stashes of food from being stolen by other birds that had watched them cache (Dally et al. 2006). The most remarkable finding was that only those birds that had had the opportunity to pilfer (steal) other birds' caches in the past engaged in these cache protection tactics (i.e., naïve birds that had not pilfered before did not do so) and that they only did so if they had been observed by a potential pilferer – they did not do so if they had cached in private (Emery and Clayton 2001). Taken together these series of findings about the extraordinary ability of corvids led to the idea that cognition must have evolved independently and probably convergently in the corvids and apes despite obvious differences in body morphology and the neuroarchitecture of their brains (Emery and Clayton 2004).

Subsequent work established that these birds can also plan ahead, not only for other times (Raby et al. 2007) but also for other minds (Ostojic et al. 2013). It was the latter research

that led to the development of the food sharing paradigm, showing that the jays can infer what their mate will desire in the future (Ostojic et al. 2013).

This work has also led to the development of new paradigms for testing humans that rely much less than conventional studies on verbal report, which have been particularly informative in bridging the gap between human cognitive development and comparative cognition (Clayton 2014) and inspiring new models for thinking about human cognition which have translational aspects – for example, the relationship not only between the hippocampus and memory but also obesity (Cheke et al. 2016; Cheke et al. 2017).

Finally, her science and art collaborations have also resulted in published papers that explore the evolution and manifestation of cognition, through the conduit of dance and with inspiration from the birds (Laland et al. 2015; Clayton and Wilkins 2017). Perhaps that is why Nicky has become known as both The Bird Lady and The Dancing Professor.

### ► Precocial

## Nikolaas Tinbergen

Rachel T. Walker

Department of Psychology, University of the Incarnate Word, San Antonio, TX, USA

Nikkolas (Niko) Tinbergen contributed to the growth of the field of ethology, a branch of zoology (born April 15, 1907, The Hague, Netherlands – died December 21, 1988, Oxford, England) (Burkhardt 2005). Ethology is the scientific study of instinctive and learned animal behavior in a naturalistic environment. Tinbergen played a role in studying animal behavior with systematic field experiments.

Tinbergen grew up in the Netherlands within a family of five children. His father was a teacher of Dutch language and literature. His family shared

his interest in nature and being outdoors. In addition to Niko's impact in ethology, his siblings Jan Tinbergen became a Dutch economist and Nobel laureate and Lukas Tinbergen was an influential ornithologist and ethologist (Burkhardt 2005; Kruuk 2003; Tinbergen 1973a). Early in life his interests were exploring fauna and flora in their natural environment while his interest in school was scarce. He was influenced during his secondary education by several individuals, Dr. Schierbeek, and C. J. Tijnstra, to name a few. They promoted his interest in nature. He finished secondary school in 1925 and then spent 3 months exploring an area where bird migration fieldwork was occurring. He then started his education at Leiden University. Later Tinbergen pursued and obtained his Ph.D. in biology from Leiden University in 1932. During his time in college, he had a tedious educational disinterest as he did during his childhood school experience. He did appreciate teachers who exposed him to animals and promoted flexibility with his outside interests. His dissertation was a relatively short paper where he examined digger wasps orientation behavior. One of the reasons for such a small project was a 1 year expedition to Greenland where one of the topics he studied was snow bunting territorial behavior. He also examined birds and Eskimos during this time. During the year that he obtained his degree, he also married Elisabeth Rutten. After his short-term project in Greenland, he returned to Leiden University in 1933, where he taught and established a program examining animal behavior. In 1936, two events influenced his future in researcher. This was the first time a course in ethology was ever offered. He also met Konrad Lorenz, who came in as an invited speaker to Leiden. This was the beginning of a collaboration between the two in the field of ethology. Lorenz had provided the theoretical concept of the fixed action pattern and the innate releasing mechanism. This lead Tinbergen's interest in the experimental exploration of these concepts. In September, 1942, Tinbergen was held hostage during World War II. When he was released, he returned to work and in 1943 the university was reopened, and he was promoted as a full professor. While his first

experience of teaching and research began at Leiden University, he later moved to Oxford in 1949 and continued to influence this field of science in England.

Due to his unique study of animal behavior, he was awarded, along with Karl von Frish and Konrad Lorenz, the 1973 Nobel Prize in Physiology or Medicine “for their discoveries concerning organization and elicitation of individual and social behaviour patterns” ([http://www.nobelprize.org/nobel\\_prizes/medicine/laureates/1973/](http://www.nobelprize.org/nobel_prizes/medicine/laureates/1973/)). Specifically, he was recognized for his research on the adaptation of gulls to ecological settings. During his time he founded the *Behaviorism* journal (1947) and published several books, including *The Study of Instinct* (1951), *The Herring Gull's World* (1953), *Curious Naturalists* (1958), *The Time-Life Volume, Animal Behavior* (1965), and *The Animal in its World* (1972, 1973b) to name a few. His final contribution was a collaborative study with his wife on early childhood autism, *Early Childhood Autism – An ethological approach* (1972).

One of his main contributions explored behavior through the breakdown of proximate and ultimate mechanisms. Within these mechanisms a total of four possible causes of behavior were described: causation, development, phylogeny and adaptation (Tinbergen 1963; Shettleworth 2010).

Proximate – the immediate causes of behavior

- Causation (Mechanism) – How does this behavior occur in an individual? How do signals and mechanisms cause the behavior?
- Development (Ontogeny) – What can effect or influence the growth or development of behaviors.

Ultimate – the adaptive significance of behavior

- Phylogeny (Evolution) – How does this behavior arise in the species? How did the behavior evolve over generations?
- Adaptive Value (Function) – Why is the behavior adaptive for the species? How does this function contribute to survival and reproduction?

One example is related to bird song; how and why do birds sing. What mechanisms underlie song production (i.e., neural, sensory, hormonal, and motor systems)? How is the song acquired and modified throughout the lifespan of the bird? What are the differences in the acoustics across a comparison of species? How does the bird song play a role in defending a territory or in reproductive success?

Another example would examine the behavior of social grooming (e.g., allogrooming) in non-human primates. What triggers allogrooming behavior? What age does allogrooming begin and which animals engage in the behavior? Does this development change depend on the environmental habitat or the type of social group? Within the comparison of different social groups, when might it change from hygienic function to a social function? Is allogrooming used to increase social bonding and health and/or reduce tension in the social hierarchy?

Tinbergen's contributions expanded the understanding of behavior in a variety of species such as black-headed gulls, graylag geese, herring gulls, stickleback fish, and digger's wasps. In each of the studies, he created systematic observations and experiments to investigate animal behavior.

## Black-Headed Gulls

Black-headed gulls naturally take empty egg shells and drop or relocate them some distance from the nest. During this time the chicks are left alone in their nest. Why do black-headed gulls remove broken eggshells from the nest after the chick hatch? This is an example of an ultimate question. Tinbergen examined why the chicks would be left vulnerable by this behavior. He found through experimental studies that the function was to decrease the predation of their offspring which was the results of an adaptive mechanism (Tinbergen et al. 1962). Tinbergen also explored how the stimuli (i.e., egg) could alter the type of behavior that the gull exhibited. He manipulated a model egg in various ways such as the color, shape, size, and distance from the nest. In doing so he measured the frequency and

latency of the specific behavior that the gull was engaged in (e.g., rolling vs carrying).

## Graylag Goose

Tinbergen also worked with Lorenz on graylag geese and their stereotypical egg rolling behavior (Lorenz and Tinbergen 1939, 1970). An automatic response of the goose exists when an egg is located outside of the nest. The automatic response of rolling the egg back into the nest was discovered to be a complex instinctive behavior. If the egg was removed during the recovery response, the goose would continue with the complex response. This is when Tinbergen and Lorenz further examined this by using a variety of egg-shaped stimuli to discover that geese continued the “fixed action pattern” regardless of if the egg was removed. This fixed action pattern was the result of exposure to a specific sensory stimulus (i.e., sign stimulus) which created an innate sequence of reflexive responses. In the study the geese were also provided multiple varieties of “eggs” outside of the nest in which the size, pattern, shape, and color were modified. Through this investigation they determined there was a preferred egg but it was not the normal egg. The artificial egg they preferred was larger, had a more complex speckled pattern, and was darker in the green color. These unrealistic cues were labeled as “supernormal stimuli.”

## Herring Gull Chicks

Another one of Tinbergen’s classic studies examined herring gulls (Tinbergen and Perdeck 1950; Tinbergen 1960). Herring gull chicks display an automatic pecking behavior to a red spot located on the mother’s beak. The mother’s beak then produces an automatic response of regurgitation. In the classic experiments, Tinbergen explored how a “model,” the position of the red spot (distance above the ground), and alternated response time could influence the pecking behavior of the chicks. He found that the location sign stimulus (i.e., the red spot) on the model played a role in the

automatic response of the chick. When the red spot was toward the bottom and end of the beak, the chicks were more likely to peck. Tinbergen also explored how a narrow boldly colored vertical stick with horizontal movement would be perceived by the chicks. He found by intensifying the color and the contrast the model became a supernormal stimulus which elicited a supernormal response. The red stick shape and contrast created more pecking than to a real beak.

## Stickleback Fish

Tinbergen also explored this topic by examining how sign stimuli could control aggressive and sexual behavior of stickleback fish. During breeding season males displayed the fixed action pattern, which changed the color of their “belly” to red. Due to the competition of territory of the males, the color red appears to be the stimulus that triggers the notable difference in territory. If another red-bellied fish, male or female, came into their territory, it created an aggressive response. Tinbergen explored what aspect of the other fish created the automatic response and discovered it was the color red (Tinbergen 1951). This indicated that it did not have to be just a fish that had the color red on it but any object with the sign stimulus (i.e. color red) in the experiment created the fixed action pattern. In relation to courtship behavior, Tinbergen found that a swollen “belly” of a model fish, in addition to the posture, stimulated the “zigzag dance” of the male. Throughout the study it was indicated that there were multiple sign stimuli that were used in the sequence of the reproduction. During the building of the egg tunnel, by the male, is when the red belly indicated territorial aggressive behavior. However, after the egg tunnel has been completed, a female approached and became the trigger or the sign stimulus (i.e., the swollen abdomen of the female). The swollen abdomen creates the zigzag dance of the male. The female is then stimulated by the red belly of the male. In this case the size of the abdomen of the female will draw the attention and response of the male, and the red belly of the male will draw in the female to the egg tunnel.

Tinbergen examined this process using a variety of models throughout this process.

### Digger Wasps: It Relates to the Landmark Use to Lay Eggs

Tinbergen also examined the homing behavior in digger wasps, specifically the use of landmarks (Tinbergen and Kruyt 1972). How do digger wasps find their homes among a variety of nests in a location?

This is a proximate question. Digger wasps lay eggs in a burrow, for predator avoidance, after which they exit the burrow and fly around to possibly locate landmarks to assist in finding the burrow. Tinbergen first explored this aspect by creating a circle of pinecones around the entrance to the burrow. When the wasp was out foraging, they relocated the circle of pine cones. They found that the returning wasp went to the location where the pinecones were relocated. Tinbergen also explored if scents, type of object, or arrangement of the landmarks provided the burrow location. Through his studies he found that scent and the type of object were not used to locate the burrows. However, when the arrangement of the landmarks was examined, it was found that this did contribute to the landmarking principle. For example, when the wasp left the burrow, it had a circular arrangement of pinecones. Once the wasp left, a triangle of pinecones were put above the burrow and a circular arrangement of rocks were placed to the side of the burrow. When the wasp returned, it traveled to the circular arrangement of the rocks.

Tinbergen's research on patterns of behavior played a role in the development of ethology, the confirmation of field research, and the development of modern behavioral ecology. Tinbergen also contributed the connection between comparative psychologists and European ethologists. His classical studies are currently involved not only in biology but also in the field of psychology. He was not only a professor and researcher; he also became a writer and filmmaker. In addition to his research contribution, he also provided interest and concern in diplomacy, goodwill, and humanity.

## NMDA Receptors

Ankit Kumar

Centre for Neural and Cognitive Sciences, School of Medical Sciences, University of Hyderabad, Hyderabad, India

## Synonyms

[N-methyl-D-aspartate receptor](#); [NMDAR](#)

## Definition

N-methyl-D-aspartate receptor (NMDAR) is an ionotropic glutamate receptor which is found in nerve cells. NMDAR is named after the synthetic agonist to whom it is selectively sensitive, N-methyl-D-aspartate (NMDA).

## Introduction

NMDAR is a glutamate-gated positive ion-channel protein, so when activated it allows

positively charged ions to flow through the nerve cell membrane. These are found in postsynaptic terminals in communicating cells throughout the brain. It is nonselective to cations such as sodium ( $\text{Na}^+$ ), potassium ( $\text{K}^+$ ), and calcium ( $\text{Ca}^{2+}$ ).

NMDAR is critical in synaptic plasticity due to its high  $\text{Ca}^{2+}$  permeability, which is important in learning and memory. This makes it one of most extensively studied ion-channel in brain. Overstimulation of NMDAR causes excitotoxicity and abnormal NMDAR functioning has been implicated in various pathological conditions and disorders including hypoxia, ischemia, head trauma, Huntington's, Parkinson's and Alzheimer's diseases.

## NMDA Receptors

NMDARs generally have a heterotetramer structure made up of two GluN1 subunits and two GluN2 subunits, which bind to glycine and glutamate respectively. Thus activation of this receptor is dependent on both neurotransmitters to bind simultaneously, which gives it a unique property and tight control of activity. There are four functional domains of NMDAR, an extracellular N-terminal domain, a ligand-binding domain, an intracellular C-terminal domain, and a transmembrane pore-forming domain. In nervous system, GluN1 subunits are only of one subtype but GluN2 has four subtypes named GluN2A–D, and thus gives diversity to NMDARs throughout brain (VanDongen and Blanke 2008) (Fig. 1).

NMDA receptors has three very important properties which makes it high-throughput receptor and critical for proper functioning of nervous system. First is, opening of this channel requires a cofactor, glycine along with glutamate, so that this channel will only function in presence of extracellular glycine. Second, this receptor has multiple cation permeability including  $\text{Na}^+$ ,  $\text{K}^+$ , and most importantly  $\text{Ca}^{2+}$ . Third, this channel has dual mode of control among all transmitter-gated ion channels because opening of NMDAR requires ligand binding as well as membrane voltage. In the NMDA-activated channels, an extra particle  $\text{Mg}^{2+}$  binds to the pore of receptor and

**NMDA Receptors,**

**Fig. 1** NMDA receptor with its two subunits GluN1 (NR1) and GluN2 (NR2A) has been activated by binding of glycine to NR1 subunit and of glutamate to the NR2A subunit (Ascher 1998)

Bob Crimi

**NMDA Receptors, Fig. 2** Coincidence detection by the NMDA receptor. The simultaneous presence of glutamate and membrane depolarization is necessary for relieving Mg<sup>++</sup> blockade and allowing calcium influx (Sweatt 2010)

blocking the current flow. Ligand binding of glutamate to receptor and depolarization of membrane expels Mg<sup>2+</sup> from the channels by electrostatic repulsion, allowing sodium and calcium to enter and maximum current flows through receptor (Kandel et al. 2000) (Fig. 2).

The NMDA-type receptor opening and closing takes place relatively slowly than other receptors and it contribute to late phase of EPSP, and this is

carried out largely by Ca<sup>2+</sup>. Thus NMDA receptor activation further leads to calcium-dependent second messenger cascade activation in the post-synaptic cells. Long-term potentiation (LTP) is NMDAR dependent in hippocampus and many other regions of brain. These biochemical reactions are important for neuroplasticity and certain long-lasting modifications in neuronal networks important for learning and memory.

## Conclusion

NMDARs play important roles in processes of plasticity both functionally and structurally in nervous system. NMDARs have some unique properties which enable them to be very important contributor in events of synaptic plasticity, such as learning and memory formation. Most prominent of these are its dual mode of activation control, high permeability to  $\text{Ca}^{2+}$  ions, and slow deactivation kinetics which allow it to change neural patterns for extended period of time and affect plasticity. Due to these properties, NMDAR hypo or hyperfunctions results in many cognitive brain dysfunctions. All the unique properties and their malfunctions make these receptors key targets of therapeutic interventions in disease conditions.

[Binomial nomenclature](#); [Biological nomenclature](#)

## Definition

Nomenclature is a system of naming any organism, based on certain a set of rules and regulations which are explicit worldwide.

## Introduction

The different life forms are known by their specific name. The term nomenclature is derived from the Latin word (*nomen + calare*) meaning assigning name to someone. Naming animals or plants is not like naming someone according to our wish, but it needs to follow ample scientific rules which biologists have formulated (Huxley 1940; Mayr 1969; Narendran 2006). Naming an organism is important for communication in order to specify the organism. Nomenclature is in fact part of taxonomy, especially in biological science. Scientific names are provided to any organism based on its taxonomy not haphazardly. For example, fruit fly *Drosophila* belongs to family Drosophilidae which include a huge number of its species distributed in different geographical conditions. Some of its commonly occurring species like *D. melanogaster*, *D. pseudoobscura*, *D. ananassae*, *D. bipectinata*, *D. malerkotliana*, etc. share taxonomically same criteria and are placed under same genus *Drosophila* and have

sufficiently been studied to explore several biological aspects.

The organization dealing with animal nomenclature is ICZN (International Code of Zoological Nomenclature) and for plants, algae, and fungi is ICNafp (International Code of Nomenclature for Algae, Fungi and Plants); previously it was known as ICBN (International Code for Botanical Nomenclature). ICNP (International Code of Nomenclature of Prokaryotes) is concerned with prokaryotes (including Archaea) nomenclature; formerly it was called as ICNB, i.e., International Code for Nomenclature of Bacteria. Since viruses have also been considered organisms, a separate body ICTV (International Committee on Taxonomy of Viruses) has been established to name them (Narendran 2006).

The term binomial nomenclature is quite popular to be used as naming to organisms; however, this should be known that the terms binomial and binominal have distinct sense in the modern scenario (Mayr 1969; Singh 2012). Now these terms do not mean same. Botany people use *binomial* term as they follow two-word nomenclatures which state that while naming a plant, one must use two separate words for genus and species. For Zoology discipline, *binominal* term is suggested that means to follow two-name patterns for naming the animals. This then allows even to use generic as well as species name by a single word (tautonym) like *Naja naja*. Thus binomial nomenclature is the correct term for botany, and binominal nomenclature is technically correct term in Zoology. A binominal name is also called a binomen (plural binomina) (Simpson 1961; Sokal and Sneath 1963; Schuh 2000).

## Binominal Nomenclature

Carolus Linnaeus in 1753 proposed the binominal nomenclature for the first time in his book *Species Plantarum* (Kapoor 1998). Conventionally every species of animal or plant must be named by using two separate names, one as generic and other as species name. Such names are always written in Latinized form.

Either the genus or species name can be derived from words in any language. While naming an animal, the following points must be taken into account (Simpson 1961; Kapoor 1998; Barrie et al. 2012):

1. Binominal names consist of two separate names, the genus name and the species name. For example, house sparrow is named as *Passer domesticus*, where *Passer* is genus or generic name and *domesticus* is species or specific name.
2. The generic name always begins with a capital letter, whereas the species name is always in lower case letters. The species name can be a noun or an adjective.
3. The binominal names are printed in italic form, and if handwritten, the generic and species names have to be separately underlined.
4. In the running text, the name may be repeated a number of times and in such condition, the generic name can be written in full the first time it is used, and then after it is written only by its first capital letter. For example, *Passer domesticus* will appear at the start of the text and then after it will be mentioned as *P. domesticus*.

The two major groups of organisms, animals and plants, are named considering certain criteria. One of them is to follow tautonym for animal's nomenclature but not for plants. Here tautonym refers to the use of same words for genus as well as species, for example, *Naja naja* (the cobra snake). None of the plant is named by using same generic and species words.

## Trinomial Nomenclature

Trinomial nomenclature refers to three-name pattern where the third name is of subspecies. Thus our own species is always named as *Homo sapiens sapiens* where *sapiens* coming after generic name is species name and the third word *sapiens* is subspecies name (Barrie et al. 2012).

## Author's Name

In several cases the name of species is followed by the name of the person who first described or reported it. For example, *Bactrocera cucurbitae* (Coquillett), here Coquillett is the name of the scientist who described *B. cucurbitae* for the first time. This method of terminology is the correct way to represent the species name.

**Use of Parentheses:** Sometimes after further research and study, some species are reassigned another genus after their first report. In case of reassigned species, the name of reviser is added after the name of original author in bracket, for example, *Hemilea bipars* (Walker 1862; Hardy 1959). This denotes that *H. bipars* was originally described by Walker in some different order, but Hardy in 1959 correctly assigned its order (Kapoor 1998). This methodology is strictly used in the field of plant science only but not in Zoology (Narendran 2006).

**Use of Square Brackets:** In Zoological nomenclature, if author's name has been taken from indirect source other than original publication, it is necessary to put in square brackets.

## Nominal Fallacy

Richard Remedios

Northcentral University, San Diego, CA, USA

The nominal fallacy is the belief that by naming something, we have also explained it. The naming of a concept does not make the meaning of the concept a self-evident truth and does not confer any explanatory power. For example, animals that live in our homes and share our lives can be defined as pets, and pets can be defined as animals that live in our homes and share our lives. Yet, by assigning a singular label for a concept, we have not gained any further insight into what an animal that lives in our homes and shares our lives, is (Eddy 2003).

As another example, we can describe a behavior as being a product of “instinct” and assume that everyone will know what set of behaviors comprise an “instinct”. But clearly, this is not true, as Kuo (1921) put it, “no two psychologists will agree upon the definition of and what constitutes human instincts” (p. 646). The same can be said for the word “group.” While intuitively understood by everyone, it is difficult to define and operationalize across different contexts (Mudrack 1989). In all cases, the more we understand about a concept, the more we also understand that assigning a label does not take us beyond the concept itself. A particular feature of the nominal fallacy is that with knowledge, a concept can be reduced to finer and finer detail categories within the concept, i.e., different levels of instinctive behavior or different types of

groups, which may be related to different mechanisms and functions, thus rendering the overall concept label unhelpful to scientific investigation.

## Problems

Why may it be problematic if some labels are broad and serve as a placeholder for a range of explanations? A key problem with nominal fallacies is stereotyping or over-generalization. Take the example of “autistic.” Autism is a now known as Autism Spectrum Disorder to take into account the wide range of features the condition incorporates (APA 2013). Describing someone as autistic or as a person with autism creates a label where the range of behaviors ascribed to the individual depends on the observer’s familiarity with traits associated with ASD. In extreme situations, one individual may be perceiving one set of behaviors as indicative of ASD and another individual may be perceiving the same set of behaviors as neurotypical. The nominal fallacy creates a situation where it is possible to wittingly or unwittingly ascribe seemingly common sense or everyday labels to diverse sets of behaviors and definitions.

## Solutions

In most cases, there is no problem with nominal fallacies; they create cognitive shortcuts for us to broadly understand everyday terms. We don’t need to interrogate the meaning of every term we encounter because to do so we would spend most of our time speculating about definitions and fail to proceed to the higher-order issue we really want to address. For example, if policymakers had to define what constituted a “group” when discussing how to address homelessness, not much would get done about resolving homelessness.

However, researchers do need to carefully define their terms. In research, this is called “operationalization.” Labels such as “group,” “instinct,” and “autistic” need careful definition. There can be no ambiguity; there can be no self-evident truths. Nominal fallacies are the enemy of clarity and exactness. Every label needs to be

precise and this makes precise labeling a friend to the researcher. Grant awarding bodies will look unfavorably on nominal fallacies, so will journals and other publication outlets of high-quality research output. Identifying what is and is not a nominal fallacy in your own line of research will help you develop and conduct better research.

## Conclusions

Linguistically, all words are labels and so all words are open to the problem of the nominal fallacy. In everyday life, we can use phrases and words that have multiple meanings because we are often not interested about the exact meaning of the word, just the category-level shared understanding of, e.g., a group.

However, in research, we cannot afford to commit a nominal fallacy because research has to be precise. Ambiguous terms lead to ambiguous interpretations, which leads to ambiguous findings. It is beholden to researchers to carefully examine the labels they use. No researchers should commit nominal fallacies.

## Synonyms

Junk RNA

## Definition

An RNA sequence not coding for a protein is termed as a noncoding (nc) RNA.

## Introduction

In general, the term noncoding RNA is used for RNA sequences that get transcribed from DNA but do not code for a protein. However, this does not imply that these RNAs do not code for any information or are devoid of any function. Studies have shown that the genome of mammals and other higher organisms gets transcribed into noncoding RNAs, which further undergo the process of splicing, leading to smaller products. The field of noncoding RNAs has progressed a great deal in the past decade due to the development of high-throughput sequencing tools and bioinformatic software (Delpu et al. 2016; <https://www.whatisepigenetics.com/noncoding-rna/>).

It is fascinating to know that a large chunk of the total RNA (around 60%) belongs to the class of noncoding RNAs. The functions of the noncoding RNAs involving complex mechanisms are gradually being understood. More or less, the

function of the noncoding RNAs has been identified as controllers of gene expression in physiology and development, including chromatin architecture/epigenetic memory, transcription, RNA splicing, editing, translation, and turnover, thus constituting a major class of epigenetic regulators. Apart from this, they are also being used as potent biomarkers for different human pathologies by pharmaceutical industries and biotechnology companies, making them a useful therapeutic approach against human pathologies like cancer (Delpu et al. 2016).

These noncoding RNAs are variable in length ranging from 20 nucleotides to a few hundred nucleotides. For an easy understanding, the noncoding RNAs will be divided here into two groups based on their lengths: small and long noncoding RNAs (Fig. 1).

## Small Noncoding RNAs

### MicroRNAs

MicroRNAs, a recently discovered class of noncoding RNAs around 22 nucleotides in length, act at the posttranslational level and have been estimated to regulate the expression of approximately 30% of all mammalian protein-encoding genes.

MicroRNAs have been shown to be involved in a variety of diverse biological processes such as cell cycle control, cholesterol metabolism, ageing, immune responses, viral replication, apoptosis, several developmental and physiological processes including stem cell differentiation, hematopoiesis, hypoxia, cardiac and skeletal muscle development, neurogenesis, and insulin secretion. MicroRNAs also play a key role in tissue differentiation and maintenance of the tissue identity, which is evident from their highly tissue-specific and distinct temporal expression patterns during embryogenesis. Furthermore, their use as diagnostic and prognostic markers for a wide range of diseases such as cancers, heart diseases, and neurological diseases is underway. However, around 14,000 microRNAs have been annotated till now, but the functions of most of them remain undiscovered (<http://www.exiqon.com/what-are-microRNAs>).

**Noncoding RNA,****Fig. 1** Classification of noncoding RNAs**PIWI-Interacting RNAs**

PIWI-interacting RNAs or piRNAs is a class of small noncoding endogenous RNAs having a length of 24–31 nucleotides acting as guardians of the genome and protecting it from invasive transposable elements in the germ line. Their association with the PIWI proteins gives rise to an effector complex, known as piRNA-induced silencing complex which is responsible for repressing the transposons via transcriptional or posttranscriptional mechanisms, thus maintaining the germ line genome integrity (Ishizu et al. 2012; Iwasaki et al. 2015). Apart from transposon silencing, piRNAs play important roles in the regulation of cellular genes and trans-generational inheritance of the memory of “self” and “nonself.” It has also been observed that animals having nonfunctional piRNAs exhibit defects in gametogenesis and sterility. Apart from their activity in the gonadal cells, piRNAs have also been found to play crucial roles in the non-gonadal cells. Their activity in the multigenerational epigenetic phenomena in worms has also been identified (Ishizu et al. 2012). However, many piRNAs have been identified, but the mechanism of their maturation and the effector phase of gene silencing still remains to be explored (Iwasaki et al. 2015).

**Small Nucleolar RNAs (snoRNAs)**

Small nucleolar RNAs (snoRNAs) are one of the most abundant classes of ncRNAs, are 60–300

nucleotide in length, and are located in the nucleolus or in Cajal bodies (Delpu et al. 2016). Human genome comprises around 300 different snoRNA sequences generated after splicing, debranching, and trimming of mRNA introns. They have been further subclassified into two main classes (1) C/D box snoRNAs and (2) H/ACA box snoRNAs depending upon their role in methylation or pseudouridylation. Eventually, these snoRNAs interact with certain proteins to form a complex called small nucleolar ribonucleoproteins (snoRNPs), which get transported to nucleolus for 2'-O-methylation (Esteller 2011; Kiss-László et al. 1996) and pseudouridylation of rRNAs. These modifications have been reportedly known to facilitate finer folding and higher stability of rRNAs (Ni et al. 1997; King et al. 2003). Further, the role of snoRNAs in the regulation of alternative splicing has also been observed.

**Small Nuclear Ribonucleic Acid (snRNA)**

**Small nuclear ribonucleic acid (snRNA)**, or **U-RNA**, is the first class of noncoding RNA molecules identified and has an average length of around 150 nucleotides. Their location has been found to be in the splicing speckles and Cajal bodies of the nucleus in eukaryotic cells. Their transcription is governed by RNA polymerase II or RNA polymerase III (Henry et al. 1998).

snRNA and some specific proteins form a complex called as small nuclear ribonucleoprotein

(snRNP, often pronounced “snurps”), which is a spliceosome and aids in the pre-mRNA processing. Their role in the maintenance of the telomeres, regulation of the RNA polymerase II and other transcription factors, RNA biogenesis, and in guiding chemical modifications of ribosomal RNAs (rRNAs) and other RNA genes (tRNA and snRNAs) has also been reported.

## Long Noncoding RNAs

### Natural Antisense Transcripts

Natural antisense transcripts (NATs) are endogenous RNAs that are found in eukaryotes such as humans, mice, yeast, and *Arabidopsis thaliana* (Vanhée-Brossollet and Vaquero 1998). They have a striking feature of having transcript complementarity to several other RNA transcripts, thereby partially/completely overlapping those transcripts resulting in a positive/negative expression of the sense gene. Furthermore, they comprise of both protein-coding and noncoding RNAs (Lavorgna et al. 2004; Osato et al. 2007). Experimental studies have shown their role in RNA interference (RNAi), alternative splicing, genomic imprinting, and also X-chromosome inactivation (Zhang et al. 2006). On the basis of their location and site of action, they are broadly divided into two categories cis and trans. If the NATs are transcribed from a different location than their targets, they are called trans-NATs, and if the transcription takes place from the same genomic locus but from the opposite DNA strand, they are called cis-NATs. Additionally, it has been observed that the trans-NATs can target multiple transcripts with a few mismatches, whereas the cis-NATs form perfect pairs (Carmichael 2003; Wang et al. 2005).

### Transcribed-Ultraconserved Regions

Ultraconserved regions (UCRs), as the name suggests, are such genomic regions with a size of 200 bp and exhibit a 100% homology between eukaryotes such as human, rat, and mouse. UCRs are known to exist in clusters, and till now, 481 UCRs have been identified excluding the rRNAs (Bejerano et al. 2004). They are classified into (1) intergenic, (2) intronic, (3) exonic,

(4) partly exonic, and (5) exon-containing subclasses (Mestdagh et al. 2010). Expression profiles of these UTRs have been useful in identifying different types of cancers in humans. Furthermore, their conserved nature also portrays that they have important roles in cell physiology and interactions with the miRNAs (Bejerano et al. 2004; Calin et al. 2007). Nevertheless, the functions of these regions are just beginning to get discovered.

### Long Intergenic ncRNAs (lincRNAs)

Long intergenic ncRNAs are transcribed from a noncoding region of DNA that is present between coding genes. These genes have been found to be rich in transposable elements (Saey 2011; <http://www.rinnlab.com/>). More than 1000 lincRNAs have been identified in the human genome as of now, which majorly reside inside the nucleus or nucleolus. One of the most studied lincRNAs is HOTAIR, which functions as an epigenetic regulator and has an important role in cancer.

### Noncoding Pseudogenes

Pseudogenes are noncoding genomic regions that originate due to duplication or the retrotransposition of an mRNA sequence into different genomic loci and still remain homologous to an ancestral gene (Delpu et al. 2016). Pseudogenes are formed when a gene is affected in such a way that it loses its function. It is usually seen that frame shift mutation or mutations in the transcription and translation control regions lead to the formation of pseudogenes. Almost, 10,000 pseudogenes are already identified in mammalian genomes to date. Multiple studies indicate that the pseudogenes control the parental gene expression by producing natural siRNAs (Sasidharan and Gerstein 2008) or antisense transcripts and by competing with miRNA binding sites on mRNA targets (Poliseno et al. 2010). Further, it is also assumed that pseudogenes can have an important evolutionary role to play.

### Circular RNAs

Circular RNAs (circRNAs) are noncoding RNAs whose 3' and 5' end are joined together by covalent bonds resulting in the formation of closed continuous loops unlike the linear RNAs. Initially, they were regarded as the structures formed due to

errors occurring during splicing, but now they are considered as important factors in gene regulation. Their conserved nature, abundance, and also stability in the cytoplasm have increased the curiosity and interest of researchers toward them. These important characteristics provide the circular RNAs multiple functions like acting as miRNA sponges or binding to RNA-associated proteins to form RNA-protein complexes that regulate gene transcription. Further, studies also indicate the role of circular RNAs in interacting with miRNAs leading to the regulation of gene expression at transcriptional and posttranscriptional level (Delpu et al. 2016). A lot of research is still underway about their use in potential disease biomarkers and therapeutic targets in case of cancer.

## Conclusion

In the recent past, an enormous amount of research has been undertaken aiming at identification and annotation of new classes of noncoding RNAs along with deciphering their complex functions. They have been identified to play roles in multiple human disorders; the most important among them is cancer. The expression patterns of these noncoding RNAs can hence be used as a powerful biomarker against some diseases. The major challenges regarding their use in the clinical practice are in vivo delivery, off-target residual effects, and efficacy. Dedicated efforts are required to curtail these challenges and develop innovative methods and techniques to help the cause.

## Nondisjunction

Suman Yadav  
Department of Botany, Institute of Science,  
Banaras Hindu University, Varanasi, UP, India

## Definition

Nondisjunction is the failure of chromosomes to disjoin during the meiotic division, which leads to formation of gametes with an extra or missing number of chromosomes.

## Introduction

In the normal process of cell division, the chromosome segregate and equal amounts of genetic material are distributed in each cell. When these chromosomes fail to separate properly, each daughter cell receives an abnormal number of chromosomes. One of the cells has many chromosomes while others have few. This improper segregation is known as **nondisjunction** that could result from improper chromosome movement, incomplete pairing, or centromere malfunction (Bridge 1913). This abnormality was discovered by Calvin Bridges in 1913 while working on *Drosophila* (Morgan 2012).

## Forms of Nondisjunction

There are various forms of nondisjunction that lead to different types of chromosomal abnormality.

### Failure of Homologous Chromosome to Separate in Meiosis I

In nondisjunction at meiosis I, a pair of homologous chromosome fails to separate and leads to production of four gametes, two will be  $n + 1$  and other two will be  $n - 1$  (Fig. 1) Fusion of normal gametes with  $n + 1$  would have trisomic ( $2n + 1$ ) zygote and with  $n - 1$ , monosomic ( $2n - 1$ ) zygotes are formed.

### Failure of Sister Chromatids to Separate in Meiosis II

During meiosis II, each cell divides and get diploid (two pairs of each chromosome) to haploid (one of each chromosome) for fertilization. If a pair of sister chromatids fails to separate properly during anaphase of meiosis II, one daughter cell will have an extra chromosome and other daughter cell will be have some chromosomes missing and rest two have normal chromosomes (Fig. 1) Fusion of normal gametes leads to one monosomy, one trisomy, and two normal diploid cell.

### Failure of Sister Chromatids to Separate During Mitosis

During the anaphase stage of mitosis, the chromatids normally separate, and each daughter cell gets one chromatid. However, when nondisjunction occurs, one cell will receive an extra chromatid and becomes trisomic, while other will have a loss of chromatid and becomes monosomic (Fig. 1). In mitosis stage, nondisjunction may also lead to mosaicism in which a tissue may contain patches of cells with some cells having normal karyotype while the others may have abnormal chromosomes. It is commonly observed in cancer.

## Nondisjunction Disorders

Brief introduction to some of the important nondisjunction disorders is mentioned below:

**Nondisjunction, Fig. 1** Nondisjunction at various stages of cell division

### Trisomy 18 Edward Syndrome

It is the second most abundant autosomal trisomy found in the population of small children. This syndrome includes severe mental and growth retardation with frequent microcephaly, myelomeningocele, omphalocele, and cardiac and renal malformations, leading to 95% mortality rate within the first year of life (Edwards et al. 1960). Trisomy 18 is caused by meiotic nondisjunction that gives rise to a gamete with an extra copy of chromosome 18, thus has 24 chromosome. When it combines with partner chromosome the zygote chromosome will become 47. In some cases, only few cells of the body get extra chromosome 18 and this is called mosaic Edward syndrome.

### Trisomy 21 Down Syndrome

It is caused by trisomy of human chromosome no. 21. Individuals with Down syndrome have three copies of all genes on chromosome no. 21 (Patterson 2009). Trisomy 21 has a significant impact on the development of many tissues, including reduction in brain volume, the size of hippocampus, and cerebellum (Weis et al. 1991). People with Down syndrome have a high risk of early onset Alzheimer's disease (AD). By the age of 60, between 50% and 70% of the people with Down syndrome develop dementia (Aylward et al. 1997). It is also associated with a number of congenital heart defects.

### Trisomy 13 Patau Syndrome

Like all nondisjunction conditions (such as Down syndrome and Edwards syndrome), the risk of this syndrome in the offspring increases with maternal age at pregnancy, with about 31 years being the average (Holland et al. 2000). Individual with this syndrome have heart defects, brain and spinal cord abnormalities, very small or poorly developed eyes, extra fingers or toes, and weak muscle tone.

### Sex Chromosome Disorders

#### Klinefelter Syndrome

Klinefelter syndrome is the most common sex chromosome aneuploidy in humans that results from the presence of two or more extra X chromosome in human male. It represents the most frequent cause of hypogonadism and infertility in men. Most cases are caused by nondisjunction errors in paternal meiosis I. It is named after Harry Klinefelter who identified the condition in the 1940.

#### Trisomy X

In this syndrome, the females have an additional X chromosome and are also known as meta-females. It occurs in about one in every thousand female birth (Tartaglia et al. 2010). The affected individual is generally taller than normal female. It is a random event and not inherited usually.

### Diagnosis

#### Karyotyping

A conventional karyotyping method is preferable for studying the chromosomal complement of human oocytes. A fixation method is used in association with R banding technique to perform detailed survey on cytogenetics of human oocytes for aneuploidy diagnosis.

#### Preimplantation Genetic Diagnosis

In this diagnosis, only chromosomally normal embryo is selected and requires in vitro fertilization to obtain embryos for evaluation. This technique is used to identify embryos at risk.

### Polar Body Diagnosis

It is a new diagnostic method for the indirect genetic analysis of oocytes, which is carried out as part of *in vitro* fertilization. The biopsy of polar bodies can be accomplished either by zona drilling or laser drilling within a very short time period (Montag et al. 2009).

### Conclusion

Nondisjunction is the inability or failure of homologous chromosomes or sister chromatids to separate during meiosis. Depending on the stage of its occurrence, it may lead to various types of disorders. Among many autosomal and sex chromosomal disorders, Down syndrome and Klinefelter syndrome are the most common. There are some diagnostic techniques that can be useful for diagnosis and prevention of these disorders like preimplantation genetic diagnosis, polar body diagnosis, etc.

## Norm of Reaction

Bernhard Voelkl  
University of Bern, Bern, Switzerland

## Synonyms

[Reaction norm](#)

## Origin of the Term

The norm of reaction is a concept helping to explain the observation that individuals of the same genotype will produce different phenotypes if they experience different environmental

conditions. The term was originally coined by Richard Woltereck (1909), who studied environmental influences on the development of clonal lines of water fleas (*Daphnia*). He observed that those animals can develop a protective shell and spines that protect them from predators. They do so, however, only in environments where predators are present. Originally Woltereck referred to the relationship between one specific environmental parameter and the phenotype as a *phenotype curve* (Phänotypenkurven) and used the term *norm of reaction* to specify the collective influence of all environmental parameters on the phenotype. However, in the same article, Woltereck concedes that the number of potential environmental factors might be close to infinite and that, for practical reasons, one can apply *norm of reaction* also to a small subset of phenotype curves or even to a single curve. The latter use of the term has been widely adopted by the research community, and *norm of reaction* has superseded “phenotype curve” for describing the relationship between a single environmental parameter and the phenotype.

Woltereck argued that it is actually the norm of reaction that is inherited from one generation to the next and that hereditary change is a modification of the norm of reaction. As such, the norm of reaction is equivalent to the concept of “genotype” introduced by the Danish botanist Wilhelm Johannsen (Sarkar 1999). While the genome was sometimes portrayed as “the code of life” or “the blueprint of the organism,” suggesting a predominantly deterministic developmental process, the reaction norm perspective emphasizes that the genotype does not instruct for a single phenotype but for the ways how development responds to environmental variation.

### Categorization and Special Cases

The existence of fine-scaled spatial or temporal variation in the environment will favor the evolution of norms of reaction that allow for phenotypic plasticity. If it is unlikely that the environmental condition will change throughout the lifetime of an individual, then this will lead to developmental

plasticity, where a certain trait emerges during development and remains unchanged for the rest of the animal’s life. The size of helmets and spines of *Daphnia* in response to predator presence are a classical example for developmental plasticity. A polyphenism is a norm of reaction where two or more discrete alternative phenotypes can be produced contingent on environmental cues during a critical phase. The development of different color morphs of several butterflies during dry and wet season is a typical example for polyphenism, environmental sex determination in reptiles and fishes another one. If it is likely that the environmental conditions change several times within the lifetime of an individual, then norms of reaction will produce reversible phenotypic traits (Piersma and van Gils 2011). Life cycle staging, like the seasonal change of fur or plumage in many mammals or birds or the seasonal growth of antlers in deer, are examples where individuals repeatedly change between distinct phenotype.

### Mechanisms

The genetic architecture underlying norms of reaction is still poorly understood. In general, norms of reaction require an integrated system of components, including a mechanism for reception of environmental cues, a system for the transduction and interpretation of the cue, and finally the cue’s target: specific genes and their products (Schlichtig and Pigliucci 1996). Environmental transduction through immediate physiological responses and hormonal cascades can lead to the up- or downregulation of gene products such as transcription factors and micro-RNAs, which in turn influence expression patterns of genes in the gene network (Sultan 2015). The regulatory networks determining the norm of reaction can include cytoplasmatic and epigenetic factors which can be either direct responses to an individual’s past or present environment or inherited from the parent generation. A phenotype must therefore be seen as the product of a complex interaction between genotype, epigenotype, parental environment, and current environment.

## Conceptualization

Woltereck visualized norms of reaction as curves which immediately suggest conceptualizing them as functions, mapping environmental parameter values onto expected trait values. Formally the norm of reaction can therefore be defined as  $f: E \rightarrow T$ , where  $f$  is the norm of reaction, the domain  $E$  is the environmental parameter, and the co-domain  $T$  is the expected phenotypic trait. This generic formulation applies both to cases where the phenotypic trait can be measured on a continuous scale and to cases of polyphenisms where only a few discrete phenotypes exist. In the latter case, the norm of reaction can be accurately described by a step function.

## Consequences for Evolution

A reaction norm perspective on phenotypic traits unifies two concepts which have often been studied in isolation or even been seen as opposing mechanisms: phenotypic plasticity and canalization. Phenotypic plasticity describes phenotype diversification due to environmental variation, while canalization describes the limitation of phenotypic variation by mechanisms that buffer development against genetic and environmental variation (Stearns 1989). Representing the norm of reaction as a function, a plastic trait would be indicated by a steep slope, while a canalized trait would have a slope close to zero, but otherwise there are no qualitative differences between plastic and canalized traits.

Acknowledging the influence that the environment has on the development of the phenotype has important consequences for our understanding of the evolutionary process. Because norms of reaction vary among individuals and because each individual will encounter different environmental conditions, the environment is not only an agent of selection but also a determinant of the range of phenotypes exposed to selection (West-Eberhard 2003).

If environmentally induced developmental variation consistently leads to adaptive phenotypes over many generations, the produced phenotypes can become genetically assimilated, such

that the environmental input previously required to produce the trait is replaced by genetic cues. This process of genetic assimilation (Waddington 1942) has the effect that phenotypes might adapt to changes in the environment before the genotypes. This phenomenon of “genes as followers” (West-Eberhard 2003) of adaptive change rather than its sole origin is a direct consequence of the norm of reaction.

## Behavioral Reaction Norm

The concept of the norm of reaction has been applied to describe the relationship between the environments experienced by a single individual and its consistent behavioral responses. This has been dubbed *behavioral reaction norm* (Dingemanse et al. 2010). The behavioral reaction norm describes how an animal behaves on average and how its behavior changes over a gradient of environmental conditions. As such, the behavioral reaction norm is not a special case of a norm of reaction but an analogous concept, describing a property of an individual instead of a genotype.

## Norm of Reaction and Reproducibility

Finally, the norm of reaction has been recognized of having important implications for the reproducibility in bioscience – specifically for in vivo research. Laboratory experiments that are conducted with inbred animals under highly standardized conditions are testing only a very narrow range of one specific norm of reaction. Independent replicate studies often fail to reproduce the original findings, though this might not necessarily indicate that the original study was biased or underpowered but rather that the replicate study was probing a different region of the norm of reaction (Voelkl and Würbel 2016).

## Outlook

One important property of the norm of reaction is its regulatory complexity as environmental cue

response system (Sultan 2015). The regulatory complexity is a product of stabilizing selection (Schmalhausen 1949), which buffers the functioning of the organism against environmental and genetic perturbations. The consequence of such a regulatory system is that environmental information contributes to the formation of the phenotype. Environmental input is essential for the developmental phenotype. Thus, the genetic code does not contain a complete blueprint of an organism, but it carries only a part of the information, while the epigenome and the environment carry complementary information. Understanding the interplay between genetic code, epigenome, and environment and its consequences for inheritance and evolution will be the big challenge for the twenty-first century.

## Novelty

Klaudia Modlinska and Wojciech Pisula  
Institute of Psychology, Polish Academy of Sciences, Warsaw, Poland

## English Oxford Dictionary

1. The quality of being new, original, or unusual
2. A new or unfamiliar thing or experience
3. An object intended to be amusing as a result of its unusual design

## Cambridge Dictionary

1. The quality of being new and unusual
2. Something that has not been experienced before and so is interesting

## American Dictionary

1. The quality of being new or unusual, or a new or unusual experience

Novelty is defined as a stimulus (object or event) that has never been experienced before or as a deviation from the expected likelihood of an event on the basis of both previous information and internal estimates of conditional probabilities (Berns et al. 1997). Therefore, a reaction to such stimuli is a memory-dependent process, and any stimulus has to be compared with what is stored in memory to assess its novelty. Detecting novelty results in an arousal of the animal's attention and triggers a response (Berlyne 1950). Responses may take the form of simple reflexes, such as tropisms, kinesis, and taxis. In organisms with a more advanced organization of behavior, responses to novelty include an orienting response, startle response, and increased exploration aimed at the new object or situation (Pisula 2009). Exploring a new object or environment mostly involves locomotion through the new situation, approaching the unfamiliar elements in a familiar situation and sensory investigation.

Attention and response to novelty are particularly common in vertebrates. These behaviors are observed mainly in mammals and birds, but research shows that the tendency to be attracted to and explore novel objects is also present in some reptiles including turtles, varanid lizards, and crocodiles (Greenberg 2003). Reactions to novelty have also been tested in invertebrates such as octopuses or cockroaches.

In contrast to a situation involving hedonic stimuli (e.g., food or mate), the effect of novelty is self-limiting, and with time the animal becomes habituated to the resulting arousal (Staddon 2016). However, novelty has its own rewarding value, independent of other properties of the stimulus. Studies on animals show that rats are willing to endure an electric shock if they are rewarded by being able to examine an unfamiliar environment (Nissen 1930). Rats also prefer to spend more time in the experimental cage compartment previously associated with novelty. However,

animals generally prefer novel stimuli of low intensity (Pisula and Siegel 2005).

Novelty can be also viewed as a source of information. Organisms regulate their behavior based on information that is constantly available to their senses. Even simple organisms have the ability to use complex behavioral regulation based on external input. The information may be conveyed in various forms, e.g., as chemical, thermal, electric, or light stimuli. However, the ability to detect the novelty of a particular stimulus requires the ability to differentiate between various stimuli. This differentiation involves a negative (withdrawal) or positive (approach) response to a stimulus, a change of direction, or the animal resuming or stopping its locomotion. The animal receives information from the environment and reacts to it depending on the capabilities of its sensory and executive apparatus.

Surprise is also one of the possible responses to novelty. This kind of arousal may be induced not only by complete novelty of the stimulus but also by some unexpected feature in a familiar object or event, by something that is to some extent similar and to some extent dissimilar to what is well-known to the animal. In this sense, novelty can be viewed as a continuum from complete familiarity to complete unfamiliarity. Moreover, animals regulate the amount of novelty through their own activity, e.g., by approaching the novel stimulus or withdrawing from an unfamiliar situation. Therefore, in the natural environment, it is unlikely that an organism will be faced with completely novel stimulation. Complete novelty would have to be defined as complete lack of expectations with respect to future stimuli. It is only possible when such a situation is artificially created either intentionally or unintentionally by humans. It is unlikely that this type of unnatural situation has played any part in the development of a stable adaptive mechanism.

From an evolutionary perspective, a reaction to novelty which involves increased exploration has an adaptive value. An animal's response to novelty results from the interaction of behaviors motivated by curiosity about the novel object's potential value and fear of possible threat, or, in other words, the uncertainty of either the costs

or benefits of approaching the novel stimulus. Detecting a potential threat triggers neophobic reactions of varied intensity. Such reactions may take the form of latency to approach a new object or to start exploring a new environment. When confronted with high-intensity stimuli, the animal may freeze or flee. There is ample evidence to suggest that neophobia (caution toward novel stimuli) is a learned response; young individuals explore new objects and environments with lower latency and higher intensity than adults. In addition, research shows that animals reared in an enriched environment show reduced neophobia in comparison with those reared in an impoverished environment. Animals inhabiting a threat-rich environment (e.g., where the risk of predation or competition is high) exhibit more caution when exploring new objects or environments (Greenberg 2003).

The neurological mechanisms underlying reactions to novelty have not yet been thoroughly examined. However, the amygdala, the dentate gyrus, and the cingulate and parietal cortices may be involved in novelty detection and the associated cognitive events (Montag-Sallaz et al. 1999).

## Definition

Nucleus is one of the most dynamic membrane-bound organelle present in the cell. During the course of evolution, packaging of nuclear material in a separate membrane inside a cell was a turning point that distinguished eukaryotic from prokaryotic organisms. It is the most important structure of the cell as it contains the blueprint of life, DNA, responsible for storage and transmission of hereditary characters.

## Introduction

The term “nucleus” is derived from Latin word *nucleus* or *nuculeus*, meaning kernel or seed. Nucleus is equivalent to the eye of cell which

contains the DNA. It is one of the most important, prominent, and first ever discovered organelle that encompasses the genetic material of the cell in eukaryotic organisms. Prokaryotic cells do not have a nucleus; their genetic material is loosely bound to their outer membrane and is called nucleoid. The DNA is contained within the walls of the nucleus forever, never leaving it; the transcribed product of the DNA, however, comes out of the nucleus to make the functional proteins. The 2-m-long DNA thread is packed inside a 6- $\mu$ m nucleus of a 60- $\mu$ m-diameter mammalian cell owing to the compaction given by binding of DNA with various histone as well as nonhistone proteins (Alberts et al. 2002).

Nucleus was first observed by Antonie Philips van Leeuwenhoek in RBCs of salmon in seventeenth century. It was also analyzed by Franz Bauer in 1804 and Robert Brown in 1831 who coined the term “nucleus,” but all of them could not assign any function to the nucleus. Further in 1838 Matthias Schleiden called it cytoblast (cell builder) proposing that the nucleus function in cell generation. Later after the discovery of other cell organelles, and increasing number of studies on cell, nucleus was recognized as a key tenet of the cell (Pederson 2011).

## Structure and Components of the Nucleus

Nucleus has been proposed as one of the complete cell organelles having its own skeleton and organelles (Lamond and Earnshaw 1998). Nucleus is enclosed by a double-layered phospholipid nuclear membrane, outer and inner, separated by a perinuclear cisternal space of 10–50 nm and is in direct connection with the inner membrane of rough endoplasmic reticulum (ER) (Rowat et al. 2008). The nuclear membrane contains nuclear pores lined by nuclear pore complex and provides a way to maintain continuity between cytoplasm and nucleoplasm (Carmo-Fonseca et al. 2002). Nuclear membrane also works as a selective barrier separating cytoplasmic and nuclear content. The outer membrane is very much similar in composition as well as

function to rough ER, containing ribosomes on its cytoplasmic surface. The inner membrane is in direct contact with nuclear lamina. Nuclear pore is a circular membrane opening, occupied by eight spokes and the central granule; it allows the passage of small water-soluble molecules (Görllich and Kutay 1999). While for the transport of macromolecules, a specialized class of transporter factors known as karyopherins is responsible. RNA synthesized in the nucleus is exported to the cytoplasm with the help of karyopherin called exportin and proteins such as histones, DNA and RNA polymerases, and transcription factors are imported into the nucleus by importins.

Another major component of the nucleus which held together all the components of nucleus is nuclear matrix. It includes nuclear lamina, nucleolar remnants, structural components of the nuclear pore complex, enzymes, nuclear membrane proteins, and an internal nuclear meshwork of fibers and fibrils (Fey et al. 1984; Tubo and Berezney 1987; Miller and Forbes 2000). Nuclear matrix helps in maintaining the structural integrity of the nucleus (Cockell and Gasser 1999) and also in regulating the gene expression (Tetko et al. 2006). Nuclear matrix proteome analysis has revealed a great deal of variation in the types of factors that are associated with it, which varied according to the need of the cell during development (Kallappagoudar et al. 2010). These factors include structural proteins, chaperones, DNA/RNA-binding proteins, chromatin remodeling factors and transcription factors, and indicator of its structural and functional significance. Nuclear matrix provides the microenvironment for the optimum functioning of the chromatin.

Nucleolus is the densely stained largest structure present in the nucleus. It is a suborganelle as it is not bound by any membrane and is mainly responsible for the production and distribution of rRNA (Boisvert et al. 2007). The nucleolus is formed in the region of the ribosomal DNA (rDNA) repeats, which cluster at chromosomal loci called nucleolar organizers, and is the region in which ribosomal RNAs (rRNAs) are transcribed, processed, and assembled into ribosome subunits (Lamond and Earnshaw 1998). Various studies have linked the morphological changes of nucleolus with cancer progression (Quin et al. 2014).

Along with the nucleolus, various other sub-cellular structures are present in the nucleus including Cajal bodies, Gemini of coiled bodies, polymorphic interphase karyosomal association (PIKA), promyelocytic leukemia (PML) bodies, and nuclear speckles, specialized for different functions. Cajal bodies (CBs) or coiled bodies are mostly present in metabolically active proliferating cells as is mainly responsible for RNA processing and telomerase assembly. PML bodies or nuclear domain 10 (ND10) or Kremer bodies are spherical structure involved in DNA replication, transcription, or epigenetic silencing. Nuclear speckles or interchromatin granule clusters are nuclear domains enriched in pre-mRNA splicing factors and are involved in regulation of gene expression (Spector and Lamond 2011).

In a eukaryotic cell, DNA complexed with protein is present in the form of chromatin which is condensed during the cell division. In a cell, 10% of the chromatin is highly condensed and darkly staining called heterochromatin, while rest is transcriptionally active and lightly stained called euchromatin (Wolffe 1992) (Fig. 1).

## Nucleus Number

The nucleus number in eukaryotes varies among different cell types and also sometimes with

different developmental stages of same cell type. Depending upon the number of nucleus in a cell, they can be categorized as anucleate, uninucleate, or multinucleate cell. Anucleate cell does not have any nucleus and thereby they are incapable of producing daughter cells. Most common examples include mammalian RBCs and sieve tube elements in plants. Abnormal cell division may also give rise to such condition in which one daughter cell has no nucleus, while the other has two. Most eukaryotic cells are uninucleate as they have a single nucleus. Multinucleate cells have multiple nucleus (two or more); examples include skeletal muscle cells and giant multinucleated cells in human, mycorrhizal cells, and some species of protozoans.

## Conclusion

The origin of nucleus in a cell was one of the landmarks in the history of evolution. Various theories revolve around the origin of nucleus, among which, the syntrophic model is the most famous, which suggests that the nucleus is a result of symbiosis between archaeon and eubacterium (Misteli 2011). The advances in the cell techniques have helped understand the dynamic roles of nucleus. It is a highly ordered structure containing various sub compartments separating proteins and other molecules to perform specialized functions. The

**Nucleus, Fig. 1** Diagrammatic representation of nucleus and its major structural components

importance of this cell organelle can be understood by the fact that removal of nucleus leads to the complete loss of structure and function of the cell.

## Nucleus Accumbens

Ankit Kumar

Centre for Neural and Cognitive Sciences, School of Medical Sciences, University of Hyderabad, Hyderabad, India

## Synonyms

[Accumbens nucleus](#); [NAc](#); [NAcc](#); [Nucleus accumbens septi](#)

## Definition

Nucleus accumbens (NAc) is a brain area found in basal forebrain. It is present in between caudate and putamen nuclei of basal ganglia. NAc is also the main component of ventral striatum. Most importantly NAc is implicated in reward pathway of brain.

## Introduction

Nucleus accumbens is part of ventral striatum in basal forebrain area of our brain. It is present in both hemispheres. It is a key structure involved in motivational, reward processes associated with psychoactive drug use. Due to a central part of reward pathway in brain, this region has been

implicated in various psychiatric and neurological diseases such as depression, anxiety disorder, obsessive-compulsive disorders, and in drug abuse and addiction. Nucleus accumbens receives input from dopaminergic neurons of ventral tegmental area (VTA) and it results in increase in dopamine levels in the NAc (Salgado and Kaplitt 2015).

## Nucleus Accumbens

The nucleus accumbens (NAc), a part of ventral striatum, is mostly involved with reward, motivation, satisfaction, motor function, and learning. NAc itself is made up of two anatomical components, a central core and an outer shell and both has different contributions to the function of nucleus accumbens. NAc core controls the goal-seeking behavior and generic motivational value whereas the NAc shell looks for novelty and controls the enhancing effect of drugs (Shirayama and Chaki 2006) (Fig. 1).

Nucleus accumbens is an important component of mesolimbic pathway (VTA-NAc) which is a major dopaminergic pathway stimulated during all rewarding experiences. This circuit is key stimulator of reward experience. Activation of this circuit tells the brain to remember the activity which resulted in particular reward and repeat it in future. Along with VTA and NAc there are several other areas of brain which contributes

significantly to overall reward experience including hippocampus, amygdala, hypothalamus, and prefrontal cortex. All of these have their distinct role in reward-seeking behavior for individuals (Shirayama and Chaki 2006).

The primary neurons in NAc are medium spiny neurons and they get projections from dopaminergic neurons from VTA area. Also medium spiny neurons project to various areas of mesencephalon and basal ganglia. The main input nucleus of basal ganglia, NAc, gets afferent projections from VTA and substantia nigra in form of dopaminergic projections and direct input in form of glutamatergic projections from subiculum, amygdala, hippocampus, thalamus, and prefrontal cortex (Brain Reward Pathways n.d.) (Fig. 2).

In terms of functional diversity, nucleus accumbens plays critical role in locomotion, learning (both conditioned place preference and avoidance), and sexual motivation, feeding behavior as well as reward and incentive. NAc was the first structure of interest to study the dopamine (DA) and dopamine receptors in various pathological states (Brain Reward Pathways n.d.). A strong body of evidence suggested that DA in the NAc plays key role in addiction. Naturally with any rewarding stimulus such as food, there is increase in DA release in accumbens but it goes down with repeated exposure. However, in case of drugs of abuse the waning of DA release does not happen with repeated exposure to drugs and leads to abuse and addiction. Drugs of

abuse also tend to change synaptic plasticity in accumbens and once an addictive behavior is learned the DA neurons fire with different spatial and temporal degrees. Dopaminergic pathway dysfunction in NAc is involved in depression-like behavior, and dopamine in NAc is prime target of therapeutic drugs for treatment in major depressive disorders (Volman et al. 2013) (Fig. 2).

## Conclusion

Nucleus accumbens is a prime area involved in major reward circuits and has influence over variety of human behaviors. It controls response to rewards such as food, sex, environments, and recreational drugs and implicated in their abuse. NAc is a major determinant of motivational and incentive-driven behaviors. It gets inputs from several regions of brain and projects to several others which makes it vulnerable to any insult or abuse and that leads to its involvement in major psychiatric and neurological disorders.

## Numerosity

Mark S. Schmidt

Department of Psychology, Columbus State  
University, Columbus, GA, USA

At the Fifth International Congress for the Unity of Science in Cambridge, Massachusetts, Stevens (1939, p. 1) proposed a distinction between the terms “numerousness” and “numerosity.” He proposed that numerousness refers to “a property or attribute which we are able to discriminate when we regard a collection of objects,” while numerosity is a “property defined by certain operations performed upon groups of objects.” For example, an operation to determine numerosity might be to count a group of objects. Twelve years later, in a footnote from chapter 1 of his *Handbook of Experimental Psychology*, Stevens (1951, p. 22) again suggested the distinction, stating that “numerousness refers to the subjective aspect or attribute that we observe when we look at, but do not count, a collection of objects.”

A perusal of the literature from mid-twentieth century to the present suggests Stevens’ distinction was never fully embraced by researchers. Numerosity is used routinely in papers from the 1950s onward to refer to the perception of the number of items in a set without counting, including studies using Stevens’ experimental methods (e.g., Abbey 1962; Cheatham and White 1952; Krueger 1972, 1982). Stevens himself, in his 1939 conference presentation, suggested the terms as a “possible distinction” and jokingly referred to both as “barbarous” (Stevens 1939, p. 5).

Krueger (1972) used the term “perceived numerosity” and in the footnote on page 1, Krueger thanks Stevens for commenting on an earlier draft of the paper. One might think that Stevens would have recommended that Krueger use “numerousness” instead of “numerosity,” and it would be interesting and informative to see what Stevens did share with Krueger in that correspondence. In Krueger’s (1972) abstract, he

also distinguishes between “apparent numerosity” and “absolute numerosity,” with the latter likely referring to what Stevens meant by numerosity and the former referring to what Stevens meant by numerousness.

In 1967, APA’s Psyc Abstracts introduced the search term “numerosity perception” to mean “perception of quantities in stimulus sets in visual, auditory, or other perceptual modes.” The term “numerousness” was apparently never added to Psyc Abstracts as a search term, and it’s also not used in the thesaurus of APA’s modern electronic database PsycINFO. A recent search for the two terms in PsycINFO (1950–present) returned 1128 abstracts containing the term “numerosity” but only 57 containing “numerousness.”

Dehaene (1997) in his book *The Number Sense* (p. 35) suggests the two terms are interchangeable: “. . . scientists, when they describe perception of numerical quantities, speak of ‘numerosity’ or ‘numerousness’ rather than number.” An example of a similar use of interchangeable terms in perceptual psychology might be “pitch” and “frequency perception.” Pitch refers to the perception of sound frequency; therefore “pitch” and “frequency perception” are referring to the same thing, and the two terms might be used interchangeably. Similarly, numerousness is the perception of numerosity (cardinal number through counting), so “numerousness” and “numerosity perception” are referring to the same thing, the perception (without counting) of the number of items in a countable set. Someone could determine the numerosity of a set by counting and then ask another person for their perception of that numerosity without counting. Some other terms encountered in the literature are “perceived numerosity,” “numerosity judgments,” “numerosity discrimination,” “numerosity estimation,” and “numerosity perception,” all of which refer to numerousness as Stevens (1939) used it. It seems that Stevens’ suggested distinction was never widely adopted, and most researchers have been using numerosity to refer to what Stevens called numerousness. It should be noted, however, that many researchers use numerousness as Stevens (1939) originally proposed (e.g., Beran 2017; Thomas and Chase 1980).

Numerosity perception has been studied and documented in a very large number of nonhuman animal species (Beran 2017) including insects (Giurfa 2019). Numerosity perception is likely a highly adaptive cognitive mechanism across a diversity of animal taxa. In several studies of animals in natural settings, researchers have concluded that numerosity perception likely enhances fitness (e.g., McComb et al. 1994), and it is easy to see how. If a fish is able to perceive numerosity and discriminate a shoal of 10 conspecifics from 15, it would make ecological sense to select the shoal with the larger number of conspecifics. Similarly, a prey animal capable of numerosity perception might be more inclined to avoid a trio of predators than a single predator. Of course, cues other than numerosity might be used in such behavioral decisions as well.

In studies of numerosity perception with nonhuman animals, it's important to attempt to rule out the possibility of other quantifiable stimulus cues correlated with numerosity, which could potentially be used instead of, or in addition to, numerosity perception. Such potential cues include the total volume of the items, the total surface area of the items, how densely packed together the items are, etc. In each of these cases, the larger the non-numerosity quantity cue, the larger the number in the set is likely to be. For example, a bowl of fruit with a large total surface area is likely to contain more individual pieces of fruit than a bowl with a smaller total surface area. Such nonnumerical quantity cues are difficult to control (Beran 2017), and compelling arguments have been made that any two sets of items differing in numerosity will always differ in one or more nonnumerical quantity cues as well, but attempts should be made to control for them. Of course, other nonquantifiable cues must also be controlled, such as the color or shape of the items. If a larger numerosity set contains only triangular or blue objects, while a smaller set contains only circular or red objects, then the two sets could be discriminated without reliance on numerosity perception at all.

Some have suggested that animals use non-numerical quantity cues readily and only resort to numerosity perception as a kind of “last resort”

when these quantity cues are not available (Davis and Memmott 1982). Cantlon and Brannon (2007) tested the last resort hypothesis in an experiment with monkeys in which color and shape could be used in addition to numerosity. The monkeys were more likely to use color or shape when the numerosity task was difficult. However, when the numerosity task was relatively easy (i.e., a large difference in numerosity between correct and incorrect responses), numerosity perception was more likely to be used, contrary to the last resort hypothesis. Beran (2017) suggested that experimental tests for numerosity perception in animals are especially difficult to design because of the task demands animals are required to learn (i.e., attending to numerosity rather than other cues).

Several mechanisms have been proposed for numerosity perception, with two receiving the most attention (Feigenson et al. 2004; Hyde 2011). One is the approximate number system (ANS; Parrish and Beran 2020). In the approximate number system, numerosity perception can be thought of as a continuous mental quantity, proportional to the absolute numerosity it represents. Smaller numerosities are easier to accurately perceive than larger numerosities, possibly because there is more “noise” in the mental representations of larger numerosities, generating more error (Gallistel and Gelman 1992). An alternative notion is that, as numerosity gets larger, noise does not increase, but the mental representations become closer together (less discriminable), making accurate numerosity perception more difficult (Dehaene 2003). Both of these ideas have received support in the research literature, and both predict the same kinds of data from experiments. Both predict that as numerosity increases, discrimination between numerosities will become more difficult, resulting in a ratio-dependent kind of performance. For example, both models predict that discrimination between a set of 6 items and a set of 12 items (ratio  $6:12 = 0.5$ ) will be easier than discrimination between a set of 9 items and a set of 12 items (ratio  $9:12 = 0.75$ ). As the ratio approaches 1.0, discrimination accuracy approaches chance level. This ratio-dependent performance is an example of Weber's Law. As long as the ratio

of the numerosities to be discriminated remains constant, performance remains constant. Ratio-dependent performance and Weber's Law have been observed in numerosity perception tasks in a variety of species (Merritt et al. 2012).

Another proposed mechanism for numerosity perception, limited to small sets of four and less, has come to be known by two names, the parallel individuation system and the object file system (Feigenson et al. 2004). In this mechanism, items are assigned mental indexes and represented as working memory files, with an upper limit of three or four files capable of being stored in working memory at any given time. Several studies have found that animals' numerosity perception is much better with very small sets of items ( $<4$ ) compared with more (e.g., Agrillo et al. 2014; Rugani et al. 2008). However, other studies have found no difference in the numerosity perception of small versus large numbers of items (e.g., Beran 2007).

The object file system shares similarities with another proposed mechanism for numerosity perception coined "subitizing" by Kaufman et al. (1949). These authors studied numerosity perception in humans and observed that, with briefly presented sets of items, response times (RTs) for up to around six items were substantially faster than for more than six. Kaufman et al. also observed that, in addition to faster RT in this range, the accuracy of participants' numerosity perception and their confidence in their accuracy were higher than with displays of more than six items. These three findings (faster RT, higher accuracy, and higher confidence) led Kaufman et al. to posit the existence of a unique numerosity perception process for small sets of items (one to six) which they called subitizing from the Latin *subitus* ("sudden") referring to the fast and accurate perception of numerosity in this range.

The existence of subitizing as a unique numerosity perception process with small numbers of items has been the subject of considerable debate and controversy. Mandler and Shebo (1982) undertook a comprehensive study to uncover the possible mechanism(s) for subitizing. In the range of one to three items, Mandler and Shebo concluded that humans quickly perceive and recognize canonical visual patterns formed

by the items (e.g., a point, a line segment, a triangle) and that it is these visual patterns that are the basis for fast, accurate, and confident numerosity perception in this range. Gallistel and Gelman (1992) theorized that subitizing in the range of one to four items is accomplished through use of a rapid, serial preverbal counting mechanism (Meck and Church 1983). The preverbal counting mechanism is prone to error, however, especially when the number of targets exceeds about four or five.

Other researchers have argued that there are no discontinuities in the RT function within the subitizing range (e.g., Balakrishnan and Ashby 1991). These authors base their conclusions on a series of statistical tests and line-fitting procedures done on the RT function for one to six items which show no significant discontinuities in the function. These authors concluded that subitizing is a capacity-limited process, and while more "mental effort" is required to perceive numerosity in larger displays compared with smaller displays, the actual mechanism is the same.

Thomas and Lorden (1993) proposed two processes for numerosity perception (they used the term "numerosness") both based on prototype matching. Relative numerosness judgments are used to discriminate the relative numbers of items in two or more sets. For example, a flock of ten birds would likely be perceived to be greater in numerosity compared with a flock of five. Absolute numerosness judgments are used when numerosity perception is applied to a single set of items, for example, a single bowl of fruit. For both relative and absolute numerosness judgments, Thomas and Lorden proposed that prototype matching is the underlying mechanism. Prototype matching occurs when an exemplar is matched against a prototype for a category acquired through experience with many other exemplars (e.g., Rosch 1975). Through training, animals may acquire prototypes for number as well and use those prototypes during absolute and relative numerosness judgments. Thomas and Chase (1980) demonstrated relative numerosness judgments, and Thomas et al. (1980) demonstrated absolute numerosness judgments, both using squirrel monkeys.

Several studies have investigated the underlying neural basis of numerosity perception in human and nonhuman animals. Two cortical areas in the parietal and frontal lobes have been most implicated (Dehaene 1997). Nieder and Miller (2004) review numerosity perception studies with monkeys where recording from neurons in the prefrontal and parietal cortices was conducted. Individual neurons were found that are “tuned” to the numerosity of items in the displays. These neurons fire faster to specific numerosities and slower to others. Parietal cortex neurons responded to numerosity more quickly than the frontal cortex cells suggesting that the parietal cells encode numerosity first and then pass that information on to the frontal cortex for subsequent decision-making.

Numerosity perception is widespread in the animal kingdom, evolving from an ancient common origin, or perhaps through more recent convergent evolution. Nonhuman animals appear to share with humans two core systems for the perception and representation of numerosity. Continued research on the mechanisms and neural bases of numerosity perception in nonhuman animals will likely provide insights regarding the phylogenetic history of this remarkable perceptual ability.

## Nuptial Gift

Jacob Pappas  
Psychology, Oakland University,  
Rochester, MI, USA

## Definition

Nuptial Gift: Materials beyond the obligatory gametes that are transferred from one sex to another during courtship or mating (Lewis and South 2012).

## Introduction

In nature, the race to reproduce is incredibly competitive. Success means an organism passes on its genes; failure means that the organism's specific genes are lost to the gene pool. One way in which an organism can increase its chance of reproduction is the presentation of a nuptial gift. Lewis and South (2012) define a nuptial gift as "...materials beyond the obligatory gametes that are transferred from one sex to another during courtship or mating." Note that this definition does not specify the sex of the giver or the receiver. Whereas male to female gifts are the most common variety of nuptial gift, some species show evidence of female to male gifts (Arnqvist et al. 2003). Male Zeus bugs (*Phoreticovelia disparata*) feed on female glandular secretions while mating. There is also precedence for nuptial gifts in hermaphroditic species (Koene et al. 2005). Earthworms (*Lumbricus terrestris*) inject their copulatory partners with a substance that increases sperm uptake.

## Diversity of Nuptial Gifts

Nuptial gifts are diverse; they can take the form of lipids, proteins, carbohydrates, peptides, uric acids, amino acids, water, pheromones, minerals, and anti-predator compounds, just to name few. Because of this diversity, it is helpful to categorize nuptial gifts in several ways. Gifts can be either endogenous or exogenous in nature (Lewis and South 2012). Endogenous gifts are gifts produced by the giver's body. Exogenous gifts are food items procured by the giver from the environment. Similarly, nuptial gifts can be oral, genital, or transdermal in nature. Oral gifts are consumed through the receiver's mouth (Gwyne 2008). Oral gifts assist the giver in mating by occupying the receiver and prolonging copulation (Lewis and South 2012). Genital gifts are consumed through the receiver's genitals. Transdermal gifts are gifts that are consumed neither orally nor genitally, but injected through the receiver's skin.

## Common Types of Nuptial Gift

**Exogenous Oral Gifts:** An exogenous oral gift is a gift that is received orally but is not created by the giver. An example of an exogenous oral gift would be food items, such as is displayed in nuptial feeding (Lewis and South 2012). In many species of bird, males provide females with food during courtship or incubation (Silver et al. 1985).

**Endogenous Oral Gifts:** An endogenous oral gift is a gift that is received orally and generated by the giver's body. Female sagebrush crickets (*Cyphoderris strepitans*) feed on wings of males during copulation (Eggert and Sakaluk 1994). Chewing on the male's wings occupies the female cricket and prolongs copulation.

**Endogenous Genital Gifts:** An endogenous genital gift is a gift created by the giver and given to the receiver through its reproductive tract. Male butterflies of the species *Heliconius melpomene* produce an antiaphrodisiac pheromone during copulation (Schulz et al. 2008). This pheromone prevents the female from re-mating by repelling would-be mates.

**Endogenous Transdermal Gifts:** An endogenous transdermal gift is a gift that is created by the giver and injected into the skin of the receiver. In some species, male squids are known to inject their spermatophores into the tissue of the female (Hoving and Laptikhovsky 2007). The spermatophore releases a structure known as a spermatangium, essentially sperm encased in a thin covering.

## Effects on Fitness

More often than not, nuptial gifts increase the reproductive fitness of the giver (Lewis and South 2012). This increase in fitness is not universal to receivers. Certainly, some receivers do increase in reproductive fitness after receiving a nuptial gift. Gifts can positively contribute to the size and number of eggs produced by a female, as well as the overall lifespan of that female (Lewis and South 2012). The longer a receiver lives, the more healthy offspring they can produce, leading to an increase in fitness. However,

some nuptial gifts decrease the reproductive fitness of the receiver (Lewis and South 2012). Male fruit flies (*Drosophila melanogaster*) prevent females from re-mating through use of a mating plug (Bretman et al. 2009). These mating plugs physically block a female's reproductive tract, with the purpose of retaining sperm. Mating plugs also prevent the females from re-mating, resulting in greater reproductive fitness for the male, allowing only his sperm to fertilize the eggs. This increase in fitness is not shared by the female, however; because she cannot re-mate, she incurs a loss in reproductive fitness.

The nursery web spider (*Pisaura mirabilis*) illustrates another form of nuptial gift that does not improve the reproductive fitness of the receiver (Ghislandi et al. 2014). Males in this species create nuptial gifts by wrapping insect prey in silk. However, male nursery web spiders have been known to deceive females by wrapping useless gifts, such as empty exoskeletons or plant materials. Whereas this behavior increases the reproductive fitness of the male without requiring a large degree of effort, the female is left without the nutritional content promised by the false nuptial gift.

## Conclusions

The need to pass on genetic material has led to many unique strategies to ensure reproduction. Nuptial gifts vary incredibly between the many species they occur in; they can be oral or genital, made by the organism or found by the organism, and can be beneficial or detrimental to the fitness of the receiver. Despite this variance, nuptial gifts share a common trait of an increase in the reproductive fitness of the giver.

## Nut-Cracking

Eduardo B. Ottoni

Department of Experimental Psychology,  
University of São Paulo, São Paulo, SP, Brazil

## Synonyms

Defended food/encapsulated food processing

## Introduction

Nut-cracking is one instance of predator-prey “arms race,” where plants mechanically defend their fruits’ endosperm, even when (or *especially* when) its outer layers are meant to be eaten by animals, for seed dispersion. Nut eaters, then, need to be able to apply the necessary force to access those endosperms, which can be accomplished by sheer bodily force alone, with the aid of gravity and hard substrates, or by using tools.

Some parrots simply crack nuts with their beaks, but tools may play a role in the technique: the oldest report of tool use by a parrot in the wild dates back to 1869, when Wallace described a black palm cockatoo (*Probosciger aterrimus*), in New Guinea, feeding from kanary nuts (*Canarium commune*). After starting to groove the nut with its lower mandible, the bird introduced a piece of leaf between the upper mandible and the nut before breaking the shell, apparently to prevent it from slipping.

Hyacinth macaws (*Anodorhynchus hyacinthinus*) exhibit a similar procedure when cracking nuts such as indaia (*Attalea dubia*), introducing leaves or pieces of wood between the nut and the beak. Borsari and Ottoni (2005) observed captive individuals holding the nuts in their beaks or feet, and slicing off a piece of wood from the perch, which was positioned, with the aid of the tongue, beneath the bird’s upper mandible. The nut was then held with the foot in contact with the fixed piece of wood. With its lower

mandible, the bird pushed the nut against the tool, grooving it with its lower mandible.

These tools may be serving as wedges, preventing the nut from slipping or rotating, or reducing the impact of the final cracking on the beak.

### Gravity-Aided Nut-Cracking

Dropping defended food, such as mollusk shells or nuts, on hard substrates is not an uncommon practice among birds. The dropping of nuts is particularly common among corvids. In most cases, it involves the selection of proper, hard substrates; there is evidence of adjustments in terms of dropping height or in the number of successive drops by the birds, as reported by Cristol and Switzer (1999), in a study on nut-cracking by American crows (*Corvus brachyrhynchos*). A typical hard substrate is asphalt roads' pavement. Nonetheless, despite a few anecdotal reports suggesting otherwise, Cristol et al. (1997) found no evidence that Western American crows (*Corvus brachyrhynchos hesperis*) deliberately used the cars to crack the dropped nuts.

In the case of Japanese carrion crows (*Corvus corone*) in Sendai, though, Nihei (1995) systematically observed the apparently intentional behavior of dropping or positioning walnuts in front of cars stopped at the red traffic lights of pedestrian crossings; after a car ran over the walnuts, the crows returned to eat the nut fragments. The author suggests the car-using behavior is an alternative invention to crack nuts too hard to be broken just by dropping (even from more than 10 m above the ground), or are still covered with pulp.

Another form of substrate use is securing the encased food in crevices to facilitate the extraction of the contents, a strategy exhibited by some seed eaters such as jays, nutcrackers, nuthatches, or pine warblers. New Caledonian crows (*Corvus moneduloides*) use these "vice-anvils" to extract the kernel of candlenuts cracked by dropping them on hard "anvils." New Zealand rooks (*Corvus frugilegus*), on the other hand, use crevices to secure walnuts while they break the shells with their beaks (Hunt 2014).

### Tool-Aided Nut-Cracking

Birds may also use stones as percussive tools to crack open defended food: Egyptian vultures (*Neophron percnopterus*) may kill lizard prey or break ostrich eggs, using stones they raise in their beaks. There are reports of American crows handling stones in their talons to hammer acorns (and of captive bald eagles doing the same to predate crickets; Shumaker et al. 2011).

The use of stone or wooden percussive tools – "hammers" and "anvils" – to access nuts' endosperm (or other defended food) is the most common form of tool use among nonhuman primates, being customarily observed in many wild populations of chimpanzees, tufted capuchin monkeys, or long-tailed macaques.

### Tool-Aided Nut-Cracking in Nonhuman Primates

*Tufted capuchin monkeys* (*Sapajus* sp.): Stone-aided nut-cracking by tufted capuchin monkeys was first studied in semifree, urban park populations (Otoni and Mannu 2001). The first direct and systematic observations in the wild were done with two populations of bearded capuchin monkeys (*Sapajus libidinosus*) in Fazenda Boa Vista (Fragaszy et al. 2004) and in Serra da Capivara National Park (Moura and Lee 2004; Mannu and Otoni 2009), both in the state of Piauí (northeastern Brazil). Tool use seems absent from forest-dwelling tufted capuchin monkeys' behavioral repertoire; the customary use of stone "hammers" to crack open palm nuts, though, is rather the rule than the exception for savannah populations (Mendes et al. 2015). The degree of terrestriality seems to be – rather than food scarcity – a stronger predictor of the use of stone percutors to process defended food in modern-day populations. The genus' evolutionary history, though – occupying savannah environments in times of intense climatic change, strongly suggests a potential role for hard-shelled fruit as fallback food in their past (Otoni and Izar 2008).

Stone tools can also be employed to process softer fruit, such as cashew nuts (*Anacardium occidentale*), to avoid contact with the irritating liquid surrounding the seed (Sirianni and Visalberghi 2013).

Field experiments have shown that tufted capuchin monkeys minimize transport costs (Corat et al. 2016); choose, transport, and use the effective tool to crack nuts when faced with stones differing in functional features (Visalberghi et al. 2009); and skillfully place the nuts so that they do not fall off the “anvil” when struck (Fragaszy et al. 2013).

*Long-tailed macaques (Macaca fascicularis)*: The only Old World species where customary use of stone tools has been observed in the wild are long-tailed macaques. Some populations of *M. fascicularis aurea*, the Burmese subspecies, use stones to detach or break oysters, gastropods, crabs, and crack open encapsulated fruit such as sea almonds (*Terminalia catappa*), transporting stones of up to 2 kg to use them as “hammers” (Gumert et al. 2009; Falótico et al. 2017).

*Chimpanzees (Pan troglodytes) and other great apes*: In captivity (or rehabilitation facilities), orangutans, gorillas, and bonobos frequently exhibit the use of percussive tools. Kanzi, the notorious, symbol-language-proficient bonobo, even produced blades by flaking stones in an experimental context, and bonobos in the “Lola ya Bonobo” sanctuary, in the Democratic Republic of the Congo, crack oil palm nuts with stone hammers; they are known to show nut-cracking behavior since the establishment of first nursery sanctuary, in 1995 (Neufuss et al. 2017). The customary use of stone tools by apes in the wild, though, seems to be restricted to chimpanzees.

Wild chimpanzees use objects as tools in a wide range of objects, usually while foraging, but also in communicative, bodily care, or other contexts. Nut-cracking with the aid of tools had already been reported in the nineteenth century; the first long-term field studies in the 1960s, such as Jane Goodall’s (1986), revealed not only the complexity of their social lives but also their technical skills – and the variation between populations (McGrew 1992; Whiten et al. 1999). The customary use of percussive tools for nut-cracking is common in West Africa (Guinea, Ivory Coast, Liberia, and Sierra Leone), though techniques and materials vary, but is virtually absent in Central and East Africa – even in places where nuts and stones are available. In sites like the Taï forest (Boesch and Boesch 1983), wooden

or stone “hammers” are usually employed to crack *Coula* nuts. For the harder *Panda* nuts, stone “hammers” are the preferred choice. Diécké chimpanzees and other populations crack these nuts with stone “hammers,” employing stone or wooden “anvils.” In Bossou (Guinea), where nut-cracking has been studied in a “field laboratory,” chimpanzees crack softer palm nuts with the aid of smaller stone tools (Matsuzawa et al. 2011). Tool use experiments have shown that captive chimpanzees actively choose appropriate stones to crack open nuts according to weight (Schrauf et al. 2012), and experienced tool users adjust their movements to optimize their performances according to the weight of the “hammer” (Bril et al. 2009). In the Ivory Coast, Taï chimpanzees transport lighter stone tools for longer distances from the source and reuse them more frequently (Luncz et al. 2016).

## Conclusion

The use of stone tools leaves lasting remains, allowing archaeological techniques to be applied in search of ancient evidence of nonhuman primates’ technology. According to archaeological evidence, Taï chimpanzees have been using stones as “hammers” and “anvils” for nut-cracking for at least 4,300 years (Mercader et al. 2007), and bearded capuchin monkeys have been using stone “hammers” to process cashew nuts for at least 700 years (Haslam et al. 2016). Although these techniques appear, thus, to be very conservative, the population differences in tool use among wild primates (McGrew 1992; Whiten et al. 1999; Ottoni and Izar 2008), along with developmental studies on nut-cracking (Resende et al. 2008; Biro et al. 2006; Eshchar et al. 2016), clearly point to, beyond genetic or ecological determinants, a socially biased learning dynamics underlying the spread and maintenance of tool use traditions among nonhuman primates.

## Nutrients

Renu Bala

Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

## Definition

Nutrients are substances which we obtain from diet, and it provides nourishment, promote growth, maintenance, and repair of body tissues (Hendrich et al. 1994).

## Nutrients

Food is one of the most basic and fundamental part of living organisms. Food provides us with the essential nutrients, which are necessary for all the biological functions of a body. Nutrients are very crucial for maintaining the structural and functional integrity of the cells. Some nutrients also function as cofactors and substrates in various biochemical reactions and pathways proceeding inside the cells or in extracellular environment. Nutrients can influence the phenotypic expression of genes by affecting processes like transcription, translation, and posttranslational modifications. The genetic makeup of an individual can also influence the response to diet (Mutch et al. 2005). Hence, it is very important to include a variety of foods in our daily diet, which can fulfill all the nutritional requirements pertaining to a healthy body. Nutrients are of different types such as carbohydrates,

fibers, minerals, fats, proteins, vitamins, and water. All these nutrients can be subcategorized into two main categories:

**Macronutrients:** They are needed in large amounts, e.g., carbohydrates, fats, proteins, and water.

**Micronutrients:** They are needed in relatively small amounts, e.g., vitamins and minerals.

Nutrients are not found in isolation except water; whereas some pharmaceutical preparations can have purified forms mixed with adequate preservatives, as in the case of supplements. Nutrients interact with each other during various processes of digestion, absorption, and transport into the bloodstream, assimilation, and use in the cellular pathways.

## Nutrition, Health, and Disease

Many studies have shown that certain nutrients act as antioxidants and protect the cells from the harmful effects of oxidative damage (Evans and Halliwell 2001). Deficiency of a single micronutrient can be easily identified and treated. But, it is often difficult to determine the subclinical deficiency of multiple micronutrients (Shenkin 2006). Hence, many countries have made separate recommendations for dietary intake of nutrients in different age groups. The values of recommended intakes of each micronutrient are set, below which a clinical deficiency state will be considered, and for the upper limits, a state of toxicity is more likely to happen. These recommendations are made based on the intakes in the healthy population coupled with epidemiological/nutrition surveys conducted in that particular population over a period of time.

## Individuals with a Higher Risk of Getting Inadequate Intakes

There are certain groups in a population that are at a high risk of getting inadequate levels such as:

People of low socio-economic status, as they cannot afford a regular supply of fresh fruits,

vegetables and other staple foods rich in micronutrients (Hoare et al. 2004).

People with chronic alcohol abuse often have multiple micronutrients deficiency due to the negligence of proper food habits (Kirby 1990). Conditions like anorexia nervosa, bulimia nervosa, and Binge-Eating Disorder (BED) are consequences of extreme efforts to control weight or food intake and are often found in adolescents and teenagers. Such conditions can result in severe micronutrient deficiencies resulting in various health complications (Sharan and Sundar 2015).

The elderly often suffer from low appetite due to age-related conditions. This lower appetite can lead to lowered food intake and hence can easily cause micronutrient deficiencies (Smithers et al. 1998).

## Individuals with Increased Demand for Nutrients

Females require higher amounts of folic acid before conception and during pregnancy especially in first trimester (Institute of Medicine 1998).

People recovering from acute illness or who went through surgical intervention might need increased amounts of specific nutrients to help them recover better and fast (Payne-James 2001).

The demand for micronutrients increases tremendously when a patient is gaining weight after a prolonged period of catabolism (Kay et al. 1976).

Loss of body fluids as in case of excessive blood loss during menstruation or other reasons can cause iron deficiency anemia in that individual. Zinc deficiency in case of diarrhea can start a vicious cycle of worsening as a result of further loss (Castillo-Duran et al. 1988).

## Micronutrient's Deficiency and Disease

Deficiency of certain micronutrients is most common in low and middle-income countries. Deficiency in any essential micronutrients can have health complications but only a few are found commonly such as folic acid, vitamin B12, iron, vitamin A and D (Shenkin 2006).

**Deficiency of various B-vitamins (Vitamin B12, B9, B1, B2, B3 and B6):** Deficiency of Folic acid (B9) and Vit B12 alone or in combination is often found to be associated with various pregnancy complications such as early pregnancy loss, preterm birth, neural tube defects, anemia, and cognitive impairment. Hyperhomocysteinemia due to deficiency of these two micronutrients is an independent risk factor for cardiovascular diseases (Shenkin 2006). Vitamin B1 and B2 are associated with Beriberi and pellagra, respectively, whereas Vitamin B3 deficiency can cause fatigue, impaired iron absorption dermatitis, eye changes, and brain dysfunction. Deficiency of vitamin B6 is common in developing countries and can cause neurological disorders, anemia, dermatitis, convulsions, and elevated plasma homocysteine.

**Vitamin D:** Vitamin D deficiency is widespread and is found in all age groups. It is associated with rickets, osteomalacia, osteoporosis, and colorectal cancer.

**Iron and vitamin C:** Iron deficiency is most prevalent among adolescent girls and pregnant females and intervention studies are still not able to control it especially in low-income countries. It can cause iron deficiency anemia, increased maternal and infant mortality, and low birth weight. Prolonged severe anemia can cause left ventricular hypertrophy (LVH), which can require hospitalization and sometimes cause death. Deficiency of Vitamin C can reduce the absorption of iron. Vitamin C deficiency is known to cause scurvy, low resistance to infection and anemia.

**Vitamin A:** Vitamin A deficiency is most commonly found in preschool children and is associated with night blindness, xerophthalmia, increased risk of mortality in children and pregnant women.

**Calcium:** Calcium deficiency is widespread and more common in old age and lactating mothers. Decreased bone mineralization, rickets, and osteoporosis are some of the symptoms associated with it (Tulchinsky 2010).

**Iodine and Zinc:** Iodine and zinc deficiency is most common in low-income countries. Iodine deficiency is associated with goiter, increased

risk of stillbirth, hypothyroidism, iodine deficiency disorders, birth defects infant mortality, and cognitive impairment. Zinc deficiency can cause impaired growth (stunting), poor pregnancy outcome, genetic disorders, and decreased resistance to infectious diseases.

**Selenium and fluoride:** Selenium deficiency can cause cardiomyopathy, increased cancer, and cardiovascular risk, whereas fluoride deficiency is associated with increased dental decay and affects bone health (Tulchinsky 2010).

### Nutritional Deficiencies in Animals

Studies have shown that poor nutrition in farm animals can adversely affect the various stages of reproduction such as delayed puberty, reduced ovulation, poor rate of contraception, followed by decreased number of successful pregnancies (Smith and Akinbamijo 2000).

Deficiency of certain micronutrients in animals is associated with various effects such as: Zn (loss of appetite, poor growth, reduced immunity, and fertility in grazing livestock), Cu (poor growth, diarrhea, anemia, and loss of pigmentation in goat), Mn (lameness), As (poor growth and abnormal reproduction in rat, chicks, and goats), and Pb (anemia, depressed growth, elevated serum cholesterol, decreased liver glucose, phospholipids, and bile acids and disturbed Fe metabolism in pigs and rats) (Alloway 2013).

### Macronutrients and Disease

**Carbohydrates:** Carbohydrates are the main source of energy, and we consume carbohydrates in the form of sugars and starch. Diets rich in refined carbohydrates and sugars can increase the glycemic index (14) (Jenkins et al. 1987). Studies have shown that diet including <3 servings per week of whole grain foods can increase the risk of type 2 diabetes. Increased consumption of whole grain foods also decreases the risk of cardiovascular diseases. High fiber, low fat, and high carbohydrate diet were found to improve the blood lipid concentration and be useful in improving intestinal disorders (Venn and Mann 2004).

**Protein:** Protein deficiency can increase in chronic illness such as infections and inflammation due to significant loss of proteins.

Excess protein can cause acidosis, azotemia, hypercalciuria, increased risk of type 2 diabetes, and cancer (Levine et al. 2014; Van Nielen et al. 2014).

**Fat:** Polyunsaturated fatty acids (PUFA) play an important role as a structural component of cell membranes and signaling molecules (eicosanoids). Some studies have shown that omega-3 PUFA has anti-inflammatory properties and might play a significant role in the management of autoimmune and cardiovascular diseases (Kris-Etherton et al. 2002; Simopoulos 2002). The higher amount of saturated fats in diet can increase the levels of cholesterol and triglycerides.

### Conclusion

It is evident that nutrients play a significant role in cellular pathways and metabolism.

Micronutrient deficiencies are much common in the general population as compared to macronutrients. The majority of food preparations are rich in proteins, carbohydrates, and fats and processed foods generally have very low micronutrients content. Hence, it is important to recognize the reasons behind micronutrient deficiency and act accordingly. It is often advisable to take micronutrient supplementation along with proper food intake if daily requirements are not being fulfilled with food alone. But one should always take supplementation under the supervision of medical personnel only. Excess consumption of supplementation without prescription can have harmful effects.

## Object Permanence

Jeroen Zewald<sup>1</sup> and Ivo Jacobs<sup>2</sup>

<sup>1</sup>Animal Behaviour and Cognition, Utrecht University, Utrecht, The Netherlands

<sup>2</sup>Department of Cognitive Science, Lund University, Lund, Sweden

### Definition

Object permanence is the capacity to represent objects as persisting in time and space independently of perception.

### Introduction

Object permanence is one of the most studied abilities in animal cognition. In the early twentieth century, researchers investigated memory by hiding a food reward in one of several opaque containers and allowing the animal to retrieve it after a delay (e.g., Tinklepaugh 1928). This research on *delayed reactions* tacitly involved object permanence, which was not explicitly considered a separate cognitive capacity until the influential

studies of Piaget (1954). He found that children develop object permanence in stages throughout early childhood. Behavioral biologists and comparative psychologists later used the Piagetian framework to document the cognitive development of various species. They discovered that not all species reach all six stages of object permanence as humans do while acknowledging that the Piagetian tasks are not suitable for many species and that numerous other factors affect performance. The debate on optimal methods continues. Recent research tries to disentangle these confounds and test animals in multiple carefully controlled conditions, with the overarching aim to describe why some species perform better than others in the light of their respective natural histories.

Piagetian Stages of Object Permanence

Piaget (1954) observed the development of his children through spontaneous behavior and informal experiments. He concluded that children, from birth to 2 years of age, progress through six stages of object permanence, with increasing cognitive demands (Table 1). In general, object permanence is tested by letting a subject search for a hidden object, which is often a toy for children

and a food reward for animals. The ability to find these rewards under various conditions indicates how well the subject understands the concept of object permanence.

Stage 1: No Response to Objects

During Stage 1, subjects are not yet capable of recognizing and searching for objects (Piaget 1954). They do not show any visual or motor responses to a surrounding object or reward. Since this is the first stage that subjects possess from birth, the criteria for this stage is that Stage 2 of object permanence has not been reached yet. Precocial animals such as chickens are more active and independent from their first day and start life at a higher stage of object permanence (Doré and Dumas 1987).

Stage 2: Visually Tracking Objects

During Stage 2, subjects still do not actively search for a disappeared object. However, they do visually track the object or reward when it is moved in their visual field (Doré and Dumas 1987; Ujfalussy et al. 2013; Zucca et al. 2007). To test this stage, subjects are presented with an object that moves through a 180° arc. The passing criterion is that the subject visually pursues the moving object (with the eye, head, or full body movements).

Stage 3: Retrieving Partially Hidden Objects

During Stage 3, subjects can retrieve a partially hidden object (Doré and Dumas 1987; Singer and Henderson 2015; Ujfalussy et al. 2013). These tests are often done by covering half of a toy or food reward with a piece of cloth (e.g., Collier-Baker et al. 2004; Pepperberg et al. 1997; Piaget 1954; Zucca et al. 2007). The passing criterion is that the subject retrieves the partially hidden reward.

Stage 4: Retrieving Fully Hidden Objects

Understanding the permanence of object entails recognizing the persistence of objects independently of perception. Unlike earlier stages, Stage 4 involves tests with fully hidden objects. Typically, the reward is fully covered by one of several opaque *occluders*, and the subject is then allowed

**Object Permanence, Table 1** Summary of the Piaget stages in object permanence. (Adapted from De Blois et al. (1998))

| Stages                          | Description                                                    |
|---------------------------------|----------------------------------------------------------------|
| 1                               | No response to the object                                      |
| 2                               | Visually tracking the object                                   |
| 3                               | Retrieving partially occluded objects                          |
| 4a                              | Retrieving fully occluded objects with initiated motion        |
| 4b                              | Understanding single visible displacement (with A-not-B error) |

| <i>Simple object permanence</i> |                                                                |
| 6a                              | Understanding single invisible displacements                   |
| 6b                              | Understanding multiple invisible displacements                 |
| <i>Full object permanence</i>   |                                                                |

to search for it (Jaakkola et al. 2010; Piaget 1954). The occluder is usually a piece of cloth, box, cup, or screen. When presented with two occluders, of which only one is baited, subjects with object permanence are expected to select the baited occluder after observing the baiting procedure. This test is usually repeated multiple times with the same subject, such that performance is reflected in a score of X trials correct out of Y trials in total, which can be statistically compared to chance level (e.g., 50% correct when two occluders are used).

Two substages are recognized. In Stage 4a, a subject is able to choose correctly but only if it initiated its movement toward that occluder before the reward fully disappeared. In Stage 4b, the subject can select the correct occluder without such initial movement (Doré and Dumas 1987; Singer 2018; Ujfalussy et al. 2013). If the reward is moved from one location to the occluder during the procedure, this is called a *single visible displacement* (Fig. 1a). Delayed response tasks in which a reward is hidden behind an occluder, instead of an arbitrary cue such as a light, involve visible displacement. Performance differs strongly among primates, but overall, they always perform better when the delay between disappearance and search is shorter (Many Primates et al. 2019). The alternative method of placing occluders over the reward does not constitute displacement because the reward remains stationary.

Piaget noticed a strange error occurring in infants of 8–12 months old. After correctly retrieving the reward at location A over several trials, subjects kept searching at location A in subsequent trials even after seeing the reward was now hidden at location B. This is called the *A-not-B error* or the *perseveration error*. Animals often make the same error (Cacchione and Rakoczy 2017; Doré and Dumas 1987; Osthaus 2017; Piaget 1954; Ujfalussy et al. 2013). Individually, these subsequent trials are still single visible displacements, but to distinguish them as a group, this procedure is called *sequential visible displacement* (Fig. 1b).

The A-not-B error becomes more prevalent with a larger number of preceding A trials, an

### A) Single visible displacement

### B) Sequential visible displacement

### C) Multiple visible displacement

**Object Permanence, Fig. 1 Visible displacements.** The most common visible displacement tasks. (a) The object is placed under an occluder. (b) The object is placed under occluder A in several trials followed by a trial where it is hidden under occluder B (as a test for the A-not-B error). (c) The object is first hidden under one occluder and then under the other occluder in the same trial. Dark objects are visible for the subject, transparent dots are intermediate positions, and light objects are in the final position

increased delay between hiding and retrieval, more complex motor requirements for retrieval, and generally if the subject is younger. This pattern suggests that the error arises from overburdened executive functions, which develop with age (Cacchione and Rakoczy 2017; Osthaus 2017). Importantly, a subject may accurately appreciate object permanence but still commit the A-not-B error because it fails to attend to the sequence, inhibit previously learned responses, remember the correct location, or perform the required actions. Methodological developments aim to reduce the impact of these confounding factors (see section “[Violation of Expectation Studies](#)”).

### Stage 5: Understanding of Multiple Visible Displacements

Stage 5 also consists of two substages. In Stage 5a, subjects successfully search the correct location in the sequential visible displacement task without making A-not-B errors. In Stage 5b, subjects perform above-chance level in a *multiple (or successive) visible displacement task* (Cacchione and Rakoczy 2017; Doré and Dumas 1987; Ujfalussy et al. 2013). Here, the reward is hidden multiple times in the same trial (Fig. 1c). Typically, the experimenter holds the reward, shows it to the subject, moves it behind occluder A, removes it, and finally places it behind occluder B. The subject should then understand that the reward is no longer at location A but at location B. A common error is searching in the first place of disappearance, resulting in below-chance performance. Animals generally perform worse on multiple compared to single visible displacement tasks (Cacchione and Rakoczy 2017). Subjects have the ability of *simple object permanence* when they passed tasks of both substages.

### Stage 6: Understanding of Invisible Displacements

In all earlier stages, the reward is always displaced in sight of the subject. In contrast, Stage 6 is tested by an *invisible displacement*; the reward is occluded during movement, and the subject has to track or infer its location (Doré and Dumas 1987; Piaget 1954; Singer and Henderson 2015; Singer 2018; Ujfalussy et al. 2013). Invisible displacements can be tested with the standard Piagetian task, the transposition task, or the rotation task.

#### Standard Piagetian Task

The standard Piagetian task has been tested most often (Jaakkola 2014). It resembles the visible displacement tasks of Stage 5 except that the reward is hidden during movements and its location has to be inferred. In Stage 6a, the subject is presented with a *single invisible displacement*, in which the reward is moved only once per trial (Fig. 2a). In Stage 6b, the subject can successfully retrieve the reward in a *multiple invisible displacement task* when the reward is invisibly

A) Single invisible displacement (Piagetian)

B) Multiple invisible displacement (Piagetian)

**Object Permanence, Fig. 2 Standard Piagetian invisible displacements.** The two substages in invisible displacement tasks. (a) The object is hidden in the displacement device and then transferred to one occluder. After that, the displacement device is shown to be empty. (b) The object is hidden in the displacement device and

then transferred to one occluder. After that, the object is transferred with the displacement device and shown to the subject after which it is hidden at another occluder. Dark objects are visible for the subject, transparent dots are intermediate positions, and light objects indicate the final position

displaced multiple times during the course of a single trial (Fig. 2b). In general, multiple occluders and an opaque *displacement device* are used. This displacement device holds the reward during movement (Cacchione and Rakoczy 2017; Jaakkola et al. 2010; Piaget 1954; Singer 2018). Often, a small container or the experimenter's hand is used as a displacement device, as both can cover the reward and move it between locations. Tasks for both substages start by the experimenter visibly placing the reward in the opaque displacement device, after which the subject can no longer see the reward. The displacement device is then moved behind or under the first occluder. In tests for Stage 6a, the reward is deposited there, and the subject is shown that the displacement device is now empty. In tests for Stage 6b, the reward is either similarly deposited behind the occluder or kept in the displacement device to be moved to the next occluder(s). The subject is then allowed to search for the reward. By tracking and inferring the position of the reward, the subject should search the occluder after which the displacement device was shown empty and thus where the reward has been left behind. Subjects that passed tasks of both substages are said to have *full object permanence*.

This task has at least five key requirements: (1) understanding that the reward continues to

exist after disappearance (simple object permanence), (2) inferring that the reward moves with the displacement device, (3) inferring that the reward has been left behind after the displacement device is shown to be empty, (4) updating the location of the reward during its movements, and (5) inhibiting prepotent responses (Cacchione and Rakoczy 2017). The third requirement is called reasoning by exclusion, which entails representing multiple alternatives ("A or B") and then ruling out one alternative ("not A"), leading to the conclusion that the remaining alternative must be true ("therefore B"). Many animals that have simple object permanence struggle with such tasks (Klerk and Jacobs 2021). Thus, the standard Piagetian invisible displacement is much more cognitively demanding than a visible displacement (Jaakkola et al. 2010).

#### Transposition Task

No displacement device is needed in the transposition task. The experimenter visibly hides the reward under an occluder and then moves the occluder(s) around (Fig. 3a). The subject can choose the correct occluder by tracking the invisibly displaced reward. There are four typical sequences in which the occluders are moved, with increasing cognitive demands (Cacchione and Rakoczy 2017; Jaakkola 2014; Majecka and

#### Object Permanence,

**Fig. 3 Invisible displacement: transposition and rotation.** The two alternatives to the standard Piagetian invisible displacement task. (a) After hiding the object under an occluder, two occluders switch positions. (b) After hiding the object under an occluder, the whole tray is rotated (180°). Dark objects are visible for the subject, transparent dots are intermediate positions, and light objects are in the final position

#### A) Single invisible displacement (Transposition, switch)

#### B) Single invisible displacement (180° Rotation)

Pietraszewski 2018; Singer 2018). The first is a *simple lateral* movement, where the occluders move laterally to a new location and the original location of the baited occluder remains empty (Fig. 4a). The second is a *lateral substitution*, where the occluders also move laterally and an empty occluder takes the original position of the baited occluder (Fig. 4b). The third is a *simple cross*, where the occluders cross during their movements and the original location of the baited occluder remains empty (Fig. 4c). The fourth movement is a *switch* or *shell game*, where the occluders also cross during their movements but an empty occluder is moved to the original location of the baited occluder (Fig. 4d).

### Rotation Task

All variations of the rotation task involve multiple occluders that are closed on all sides (e.g., cups or boxes) and do not use a displacement device. The

occluders are placed on a flat platform that can easily be rotated. One occluder is visibly baited with the reward. Instead of moving the occluders individually as in transposition tasks, the whole platform is turned (Fig. 3b). After it has been turned, the subject is allowed to search the occluders for the reward. The most common rotations are 90°, 180°, and 360°. Animals generally perform better after a 90° rotation, where both occluders move to new positions, than a 180° rotation, where the occluders switch positions (Jaakkola 2014; Singer 2018). However, a methodical disadvantage of the 90° rotation task is that one of the occluders is behind another and is therefore less visible and accessible (Jaakkola 2014).

### Task Comparisons

These different methods of invisible displacement appear to have different demands. The standard

### Object Permanence,

**Fig. 4 The four types of transpositions.** The initial setup with movements is presented in the left column, and the final situation is shown in the right column. (a) Simple lateral transposition, where the cups do not cross and the originally baited position remains empty. (b) Lateral substitution, where the cups do not cross and the originally baited position is taken by an empty cup. (c) Simple cross, where the cups cross each other and the originally baited location remains empty. (d) Switch, where the cups cross each other and the originally baited location is taken by an empty cup

Piagetian task is challenging as it involves complex nested movements with invisible transfer of the reward, and it requires inference that the reward was removed after observing the empty displacement device. Transposition and rotation tasks do not have this nested invisible transfer, but they involve more moving occluders. The sequential movements of transposition tasks may be easier to attend to than the simultaneous movements of rotations (Cacchione and Rakoczy 2017; Jaakkola 2014). Thus, the tasks differ along multiple dimensions that may have divergent effects on different species. Moreover, each task may be passed by using different cues and heuristics, which are discussed further below (see section “[Methodical Issues and Improvements](#)”). Children – but not great apes – perform better in the standard Piagetian task than the switch version of the transposition task. The 180° rotation task was found to be most difficult by both apes and children (Barth and Call 2006; Jaakkola 2014). Species comparisons on transposition tasks show that apes perform better than monkeys, which in turn outperform dogs, and that cross and switch conditions are overall most challenging (Majecka and Pietraszewski 2018).

## Development of Object Permanence

Piaget formulated the stages of object permanence as a developmental sequence in children. Uzgiris and Hunt (1975) further developed these methods with a clearer scoring system and split the different stages in 15 tasks. Each subject was repeatedly tested on a task and proceeded to the next task when successful in the majority of trials. As a result, these tasks were ordered by cognitive demands based on performance (Jaakkola 2014; Uzgiris and Hunt 1975).

Animals have been tested in similar developmental studies (Doré and Dumas 1987; Pepperberg et al. 1997). The focus lies less on when a species passes a certain stage, which is not a particularly meaningful measure, and more on whether a certain stage is passed and in what order (Pepperberg 2002). Knowing the “final stage” of multiple species can be used to

determine coupled abilities, ecological relevance, and evolutionary history. Studies have been done on many mammal and bird species (Barth and Call 2006; Collier-Baker et al. 2004; De Blois et al. 1998; Lambert et al. 2019; Pepperberg et al. 1997; Ujfalussy et al. 2013; Zucca et al. 2007). In general, adult great apes, parrots and corvids reach Stage 6 and perform better than their close relatives. Object permanence develops in a similar sequence across species, except that some species do not reach later stages and precocial species start life in a stage later than the first. Its developmental speed generally reflects the life history of the species, with faster developing species also reaching the final stage faster (Doré and Dumas 1987; Jaakkola 2014; Lambert et al. 2019; Pepperberg 2002).

Most studies focus on the visible and invisible displacement tasks and do not test the entire range of Uzgiris and Hunt’s or Piaget’s tasks (Cacchione and Rakoczy 2017). Thus, studies often neglect earlier stages, which complicates inferring the animals’ motivation and ability to track and retrieve objects. An animal with full object permanence may seem to lack this ability when not showing sufficient attention and motivation during testing. Similarly, inability to retrieve objects and remove occluders in experimental conditions may give the false impression that object permanence is lacking (see section “[Violation of Expectation Studies](#)”). Thus, these aspects should be addressed to avoid false negatives – especially for younger animals in developmental studies. Future studies should therefore test visual tracking for monitoring attention and use transparent occluders to document motivation and ability to retrieve the reward when it remains visible.

## Adaptive Significance

Although much research has focused on the maximal stage a species can reach, only little attention has gone to the potential adaptive significance of reaching a certain stage. Achieving the first stages, and doing so at an early age, is certainly crucial for various survival skills of visual animals. The later ability to represent temporarily

unperceivable agents and objects also has clear benefits in many situations, such as foraging, predator avoidance, and social behavior. An animal sticking its head in the sand to evade predators like the proverbial ostrich would not be long for this world. Nonetheless, empirical studies on the adaptive significance of object permanence are scarce, and explanations for its phylogenetic spread are speculative. Visible and invisible displacement have been discussed most in this context.

### Visible Displacement

Understanding visible displacements is an ability reached by species of many taxa, such as great apes, monkeys, dogs, cats, parrots, pigeons, chickens, corvids, and fish (e.g., Cacchione and Rakoczy 2017; Collier-Baker et al. 2006; Fiset and LeBlanc 2007; Jaakkola et al. 2010; Jaakkola 2014; Majecka and Pietraszewski 2018; Singer and Henderson 2015; Sovrano et al. 2018; Ujfalussy et al. 2013; Zucca et al. 2007). Simple object permanence thus seems common – if not universal – across mammals and birds, and a wider phylogenetic spread would not be surprising given its benefits. Moving prey visibly displaces themselves to an observing predator, which will hunt more efficiently when attending to this movement and correctly locating the prey in the new hidden location, such as behind a tree or in a burrow (e.g., Osthaus 2017; Sovrano et al. 2018). Similarly, prey species can evade predators better by continuously updating their location and movement. Representing visible displacements also has benefits for social animals, such as when avoiding competition or keeping track of offspring without the requirement for constant perceptual feedback (Jaakkola 2014). Memory is crucial in all these situations and is clearly a limiting factor in visible displacement tasks that impose time delays (Cacchione and Rakoczy 2017; Many Primates et al. 2019).

Caching birds store, remember and retrieve many hidden food items to survive food-scarce periods. Hypotheses on species differences in object permanence abilities often invoke caching propensity, but the results are mixed (e.g., Ujfalussy et al. 2013; Zucca et al. 2007), which

suggests that a different factor primarily drove the evolution of representing hidden objects. Animals may rely on various cues and heuristics that do not involve advanced levels of object permanence, as outlined in the next section. A possible explanation for species reaching later stages is that they may experience objects and agents disappearing in a large variety of contexts that warrants more flexible responses; a stereotypic or learned response might not suffice. Future studies should test such ecological and evolutionary hypotheses in more detail.

### Invisible Displacement

Understanding an invisible displacement means tracking the movements of an object even when it is not directly perceivable (Cacchione and Rakoczy 2017; Piaget 1954; Singer 2018). Its occurrence and significance in nature may be rare because target objects are not often concealed by a moving “occluder.” A baby marsupial in the mother’s pouch is one example. Prey species often move when not perceivable by a predator, but this does not constitute invisible displacement as defined in the literature. For instance, a vole escaping through a burrow is not invisibly displaced in this sense because the “occluder” (i.e., the burrow) does not move. Instead of invisible displacement, a predator could use *trajectory extrapolation* to predict where the vole might end up (Jaakkola 2014; Johnson et al. 2015). Under most circumstances, the most adaptive response to something disappearing out of view may be searching where it was last seen, which would be a failure in most invisible displacement tests. The adaptive significance of invisible displacement is more often viewed as arising from broader representation or abstraction abilities than as an isolated skill (e.g., Collier-Baker et al. 2006; Suddendorf and Whiten 2001).

Mental *secondary representation* of an object is required to understand it continues to exist and can move when not perceivable (e.g., Fiset and LeBlanc 2007; Suddendorf and Whiten 2001). For example, a subject needs to appreciate the continued existence of the reward in the displacement device and that it moves with it in the standard Piagetian task. It also needs to understand

that the reward can stay in the displacement device or move out of the device and stay behind the occluder (Cacchione and Rakoczy 2017). These are two hypothetical models that the subject needs to bear in mind and then infer which model is correct. Thus, this secondary representation adds the ability to mentally create hypothetical models, to conserve those multiple models, and to adjust them through deduction (Collier-Baker et al. 2006; Suddendorf and Whiten 2001). Secondary representation is defined as the capacity to consider multiple models of the world rather than relying only on immediate perception to guide behavior. It is a cognitively complex ability that only a few species have reached in Stage 6 object permanence tasks (e.g., Collier-Baker et al. 2006; Jaakkola et al. 2010; Jaakkola 2014; Singer and Henderson 2015; Zucca et al. 2007).

Many cognitive skills of humans have been linked to secondary representation, and it is therefore no surprise that they emergence at the same time during development (Cacchione and Rakoczy 2017; Suddendorf and Whiten 2001). Full object permanence develops in children around the age when they also develop mirror self-recognition, means-end reasoning, imitation, symbolic thought, and language (Collier-Baker et al. 2006; Jaakkola et al. 2010; Suddendorf and Whiten 2001). Most of these cognitive skills are also found to some extent in great apes and corvids, which is similar to the spread of full object permanence (Collier-Baker et al. 2004; Lambert et al. 2019; Suddendorf and Whiten 2001). Each skill is beneficial in a different way, but all fit under this wider representational umbrella. Although the adaptive significance of understanding invisible displacement is not well studied – and could be marginal due to such contexts being rare in nature – this perspective may better explain its evolution. However, it is also possible that these skills are a by-product of another cognitive skill that has not yet been recognized as such (Ujfalussy et al. 2013) or that successful test performance arises from cognitive “shortcuts” such as using cues and heuristics (see below). The methodology of object permanence tasks has therefore been regularly scrutinized.

## Methodical Issues and Improvements

Piaget created a useful framework to test object permanence in many species. Although it is still used, it is also frequently criticized. Critics mainly call for conceptual clarification and reduction of alternative explanations through control experiments and analysis of multiple variables (e.g., Cacchione and Rakoczy 2017; Jaakkola 2014). Without control conditions, the cognitive abilities of successful subjects may be overestimated (false positives); there are numerous reasons why a subject performs well on a task, with representation of object permanence being one of many. The risk for false negatives should also be considered; animals with the ability in question may still perform poorly when the testing procedure is unsuitable or unnecessarily complex (e.g., Cacchione and Rakoczy 2017; Pepperberg 2002). As in all experimental paradigms, these risks need to be understood and balanced. The four main critiques are nonvisual perception, social cues, associative learning, and sensorimotor incompetence.

### Nonvisual Perception

Humans are primarily visual creatures, so when we think of objects not being perceivable during tests, we intuitively think of them as being out of view sight. Although some cues are necessary for the subject to base the search on (e.g., perceiving the hiding process), other unintentional cues can still help subjects with perceiving hidden objects, which is a risk of any testing condition – especially when species are involved that have excellent nonvisual senses. These animals may appear to have outstanding object permanence abilities when they in fact perceive the hidden object in ways that experimenters failed to take into account.

### Olfactory and Auditory Cues

Sound and odor are probably the most influential nonvisual cues in comparative research. Preventing these cues can be done in three main ways. First, study designs can aim to *minimize the presence of a cue*. For example, occluders can be made airtight or soundproof. The subject

can also be separated from the experimental setup by a transparent wall that blocks these cues. Second, researchers can *oversaturate the setup with a cue*. In many studies, the scent of the reward is spread around all materials and will thereby mask the scent of the goal reward during testing (e.g., Zucca et al. 2007). Similarly, use of auditory cues can be minimized by playing ambient sounds during testing. Experimenters can also perform the same manipulations at each occluder, which should produce the same sounds in each case. Third, studies can actively *test for the influence of a cue*. This is typically done by secretly changing the location of the reward or by hiding it out of view of the subject. Thus, the subject cannot deduce the correct location with object permanence. Successful above-chance performance over repeated trials then suggests the subject located the reward through a nonvisual cue (e.g., Uzgiris and Hunt 1975; Zucca et al. 2007). These three methods of controlling for nonvisual cues can be used separately or combined (Collier-Baker et al. 2004).

#### Potential Influence of Other Senses

Smell and hearing are probably the most important senses to consider in a task design for object permanence. However, many animals have senses that humans do not possess or have a wider range and higher sensitivity of senses shared with humans (Keeley 2015). For example, some sharks and migratory birds can perceive magnetic fields, which makes it inappropriate to use magnets to hold and move objects and occluders (Jaakkola 2014). Echolocation is another sense that can distort results on object permanence tests (e.g., Keeley 2015; Singer and Henderson 2015). To minimize the use of echolocation, the test can be conducted in a different medium. For instance, testing materials were placed on land for cetaceans, so they could not use echolocation to find the hidden items (Jaakkola et al. 2010; Singer and Henderson 2015). Other potentially influencing senses are the ability of “remote touch” (where species use their specialized beaks to sense vibrations of nearby moving prey), detecting thermal infrared waves of objects, or sensing electric signals from the nerves of prey animals (Keeley

2015). The potential problem of these senses is species-specific, so it is important that experimenters are familiar with the sensory abilities of their study species. The kind of senses that representations are built on is another important line of enquiry: true object permanence means representing objects as permanent multimodal entities, but the question of whether animals recognize object cross-modally has received little attention.

#### Social Cues

Animals may also perform well on object permanence tasks by using social cues that are (unintentionally) produced by the experimenter. These cues are mainly found in gaze direction and body posture (Jaakkola 2014; Pepperberg 2002). Conspecifics may also provide inadvertent cues that reveal the location of a reward, so subjects should be tested in individual settings where possible. Controlling for social cues produced by humans and conspecifics is an important method to reduce the likelihood of false positives.

Four main methods are applied to prevent social cueing (Jaakkola 2014): shielding gaze direction, averting gaze, shielding body posture, and using multiple experimenters. First, experimenters can ensure that subjects cannot see their gaze by shielding their eyes. For example, the experimenter can wear mirrored sunglasses (Pepperberg et al. 1997) or a welding mask (Collier-Baker et al. 2006). This is also necessary for other people present, such as pet owners, who can be blindfolded (Collier-Baker et al. 2004). However, welding masks and mirrored sunglasses can distract or scare animals, which should therefore be well habituated to the shielding method. Some animals learn to find hidden food through reflections and mirror images, which needs to be avoided in this context. Furthermore, only humans appear to treat (human) gaze alone as a salient cue. Great apes tend to react more to head direction, whereas human infants focus mostly on gaze direction (Tomasello et al. 2007). Covering the experimenter’s eyes will remove only gaze direction but not head direction as a cue. Thus, while most studies cover the experimenter’s eyes to prevent gaze cues (Jaakkola 2014), this might

not be sufficient as subjects may use head direction as a cue instead. A second control method is to have the experimenter look away from the setup (e.g., Zucca et al. 2007). Averting gaze can help against social cueing for both eye and head directions, although unintentional glances might occur as the experimenter needs to monitor and control the test. Furthermore, body posture can still give cues to the subject with both methods.

Third, the body of the experimenter can be shielded with a screen or curtain to avoid cuing with body posture (e.g., Collier-Baker et al. 2004; Fiset and LeBlanc 2007). Although this method reduces many social cues, it may also distract subjects when they are not familiar with partially occluded humans. A decrease in attention to important events during the experiment brings about a higher risk of a false-negative result. Moreover, the position of the experimenter can still be used as a cue. A fourth method is to use a *conductor-asker* setup (Jaakkola 2014). The conductor performs the experiment as usual but then leaves the room. The asker then enters the room and prompts the subject to make a choice. This asker does not know where the reward was hidden and thus cannot provide cues – not even cues that do not involve gaze or body posture. Although this setup makes sure that social cueing does not happen, it also complicates the task. It might be hard to teach the subject the procedure and to have it understand when it is “asked” to select or search. The switch of researcher may also be confusing or distracting. Moreover, there is a longer waiting period before a selection can be made, which may decrease performance and requires more inhibitory control (Cacchione and Rakoczy 2017; Osthaus 2017). Experiments that do not involve humans or rely less on demonstrations by an experimenter carry a lower risk for social cuing (see section “[Violation of Expectation Studies](#)”).

### Associative Learning and Strategies

Animals can learn to choose the correct occluder without representing the location of the hidden object (Cacchione and Rakoczy 2017; Collier-Baker et al. 2004; Jaakkola 2014; Singer and Henderson 2015). They will appear to possess

object permanence but in fact merely act on learned associations, rules, biases, or heuristics. The ability to solve a task through these strategies risks a higher chance of false positives and should therefore be taken into consideration.

When representing object permanence, the subject is expected to solve each task rapidly with only a few trials to adjust to the setting. More trials will create a greater likelihood that subjects can learn an associative rule, which is a weakness of the Uzgiris and Hunt scales (Cacchione and Rakoczy 2017; Doré and Dumas 1987). Therefore, most studies use a minimal number of trials and look for learning effects, such as a positive correlation between trial number and performance (Doré and Dumas 1987; Jaakkola 2014). Learning may also explain better performance in conditions or stages that are tested later in a test sequence. This effect can be investigated by counterbalancing testing order across subjects. If they all perform better in later tasks, regardless of condition, a learning effect is apparent. Another suggested improvement to reduce associative learning is to never show the correct location of the reward after the subject has chosen the wrong occluder (e.g., Zucca et al. 2007). The advantage of this is that associative learning will become harder and there is a lower risk of carryover effects between trials (e.g., selecting the occluder that was correct in the previous trial). However, this method may also reduce motivation. A stronger case for object permanence can be made when success is maintained across context, with different materials, rewards, experimenters, positioning, and conditions. Next to these general suggestions, many studies have also aimed to directly control for known associative rules.

### Select the Occluder Manipulated by the Experimenter or Visited by the Displacement Device

Typical tests of object permanence are done by placing a reward in, under, or behind an occluder. Thus, only one occluder is manipulated by the experimenter or visited by the displacement device. In this context, a subject can be highly

successful by always selecting the occluder that was manipulated last by the experimenter or visited by the displacement device (Doré and Dumas 1987). This can be avoided by manipulating all occluders and by letting the displacement device visit all occluders, preferably in a random order (Jaakkola 2014; Zucca et al. 2007). It is important that the experimenter performs a sham manipulation or transfer with every occluder, where similar actions to a normal manipulation or transfer are done, without actually transferring the reward. The saliency of the manipulation may also play a role. For instance, hiding a reward behind a stationary barrier or screen is likely a less salient cue than lifting an inverted cup, placing the reward, and then placing the cup over it. Placing two occluders simultaneously, with one thereby covering the previously visible stationary reward, is another approach. Nonetheless, subjects may still succeed by using associations or learned rules such as always searching in the general area where the reward was last seen, which would be an adaptive response under many natural circumstances. Similar to other methodological issues, eliminating potential cues is difficult – if not impossible – but they can be reduced.

#### Select the Occluder Last Visited by the Displacement Device

Using the order of events or manipulations can be another successful approach. Always selecting the occluder last visited will result in perfect performance when there are no movements after hiding the reward (Collier-Baker et al. 2004; Jaakkola 2014; Zucca et al. 2007). This can be countered with a *drop-first control* (Fig. 5a). For this control, the experimenter moves the baited displacement device behind an occluder, transfers the target reward behind the occluder, and shows the empty displacement device to the subject. The displacement device then continues to the next occluder where a sham transfer is performed, after which the subject is again presented with an empty displacement device. This sequence is repeated until all occluders have been visited by the displacement device (Collier-Baker et al. 2004; Jaakkola 2014; Zucca et al. 2007). A subject using the “select the last occluder visited” rule will never choose the correct location first.

#### Select the First Occluder Visited by the Displacement Device

Another frequently successful strategy is to choose the occluder first visited by the

**Object Permanence, Fig. 5 The drop-first and drop-last controls.** (a) The object is hidden in the displacement device and then transferred to one occluder. Then, the displacement device is shown to be empty, and it continues to the next occluder(s). (b) The object is hidden in the displacement device and then transferred to one occluder.

This sequence is repeated for each occluder, and the reward is deposited behind the last occluder, after which the displacement device is shown to be empty. Dark objects are visible for the subject, transparent dots are intermediate positions, and light objects are in the final position

displacement device. In the *drop-last control* (Fig. 5b), the experimenter moves the baited displacement device behind an occluder, then performs a “sham transfer,” and reveals the displacement device to be baited. This sequence is repeated at every location until the last occluder, where the reward is transferred behind the occluder. Following the *first-visited rule* will no longer be viable in this control. However, this control method is underrepresented in most studies, which weakens interpretations of full object permanence in invisible displacement tasks (Jaakkola 2014). Gaining more solid evidence is possible by testing an intermixed series of drop-first, drop-last, and maybe even drop-middle controls (Collier-Baker et al. 2004, 2006).

#### Select the Occluder Adjacent to the Displacement Device

Subjects that fail more complex object permanence tasks often attend closely to the location of the displacement device at the end of a trial (Cacchione and Rakoczy 2017; Collier-Baker et al. 2004). They tend to search the occluder adjacent to the displacement device first. These animals appear to link the displacement device to the reward and then search in its vicinity, using the position of the displacement device as a landmark that indicates the baited location (Fiset and LeBlanc 2007). The displacement device should be removed to reduce use of such spatial cues. Although results do not show consistent effects, chances of another possible associative strategy are reduced by removal of the displacement device before a choice can be made (Collier-Baker et al. 2004; Jaakkola et al. 2010).

These are some of the most common controls for associative learning, and more are possible. However, it should be noted that such tasks can become too complicated to solve and that subjects may not be attentive or motivated enough to participate in all conditions. Studies should be adjusted to the species, and a mindful balance between avoiding false positives and false negatives can be achieved by considering the effects of these confounding factors.

#### Sensorimotor Incompetence

The Piagetian tasks were originally designed for human children and proved a great inspiration for studies on other species. However, the difference between species in sensorimotor competences should not be neglected (Cacchione and Rakoczy 2017). These object permanence tasks are suitable only for visual species, even though understanding that objects endure is beneficial to less visually adept species, and tasks can be redesigned to suit them. These tasks also require animals to select an occluder or remove it. Selection by human infants is traditionally shown by uncovering an occluder with their hands (Piaget 1954). However, uncovering occluders is not always easy for animals that are less anatomically suited for such behaviors (e.g., Fiset and LeBlanc 2007). Therefore, the sensorimotor capacities of a species should be a key factor in study design. Selecting an occluder is generally easier than removing it. Each subject can first be trained to touch an occluder and receive the hidden reward before formal testing begins.

Although many researchers take the species-specific differences in physical competence into account, it is often overlooked how this competence differs within species, especially during development (Baillargeon 1987; Cacchione and Rakoczy 2017; Pepperberg 2002). These animals may fail on an object permanence task because they cannot remove or select their choice, but that does not mean they consider the hidden object to have vanished. Some studies have tried to minimize the demands on physical competence with a new group of methods: violation of expectation.

#### Violation of Expectation Studies

Contemporary theories of object cognition build on the Piagetian tradition but differ in substantial aspects. Core knowledge theorists postulate that cognition consists of several domain-specific core systems that represent fundamental aspects of the environment, such as objects, geometry, numbers, and agency. Much like adults, human infants represent objects as entities that are cohesive (enduring as discrete units), bounded (having a

boundary that cannot be occupied by other objects), spatiotemporally continuous (persisting over time and space), and material (consisting of matter with mass). Each aspect of core object cognition – particularly spatiotemporal continuity – corresponds to some degree with Piagetian object permanence. Thus, developmental research often specifies what aspect is under investigation, rather than using the less specific term “object permanence.” Compared to the Piagetian framework, examining core knowledge is not as dependent on sensorimotor interactions and search behavior and therefore employs less action-based measures – such as looking time – that have lower motoric and executive demands (Baillargeon 1987; Cacchione and Rakoczy 2017).

Violation of expectation (VoE) studies compare how long subjects look at possible and impossible outcomes of an event. The possible outcome follows the expected persistence of objects across space and time. The impossible outcome does not follow these principles and is orchestrated through various secret manipulations. Subjects are expected to look longer when “tricked” by the impossible outcome, compared to the possible outcome that closely resembles the impossible one (Baillargeon 1987; Müller et al. 2011). The rationale behind this method is that a subject will react similarly and look equally long to the possible and impossible outcomes when it does not have object permanence.

Developmental psychologists first designed VoE methods to study infants younger than the age at which they actively make choices in traditional Piagetian tasks. This benefit extends to

animals, especially when they are similarly early in development or when the species is not suited for choice tasks. Although this procedure is less common than the standard Piagetian tasks, it holds many advantages, such as lower sensorimotor demands and reduction of social cues, non-visual perception, and strategy use. Learning still occurs but forms an important component because subjects are expected to initially show great interest in the impossible outcome, which will diminish with increasing exposure (Baillargeon 1987; Cacchione and Rakoczy 2017). These benefits are especially welcome when studying infant animals; they merely need to attend to the event, which is possible after reaching Piagetian Stage 2. The VoE method is mainly applied in three components of object knowledge: continuity, constancy, and solidity.

### Violation of Object Continuity

Object continuity is the principle that an object continues to exist independently of perception. This principle is under investigation in most traditional tests of object permanence. In VoE studies, a standard displacement task is performed, but the reward is secretly removed or moved to another occluder. A subject with sufficient understanding of object continuity will expect the reward to be behind the original occluder (Fig. 6b). When the experimenter uncovers the empty occluder in the impossible event (Fig. 6c), the subject may be “surprised,” as revealed by longer looking times and other key behaviors such as strong arousal. In other words, its expectation was violated.

**Object Permanence, Fig. 6 Violation of object continuity.** (a) The target object (red circle) is hidden behind an occluder. The subject then watches either (b) a possible outcome, where the target object appears again, or (c) an

impossible outcome, where the target object has seemingly disappeared. This method can further be combined with manipulations from traditional tests, such as visible and invisible displacement

Although this paradigm comes closest to the standard Piagetian tasks, it has rarely been studied directly. Most comparative studies have used it as a control for nonvisual cueing, but few studies report the difference in reaction or looking times of the subjects between the possible and impossible outcomes (but see Zucca et al. 2007). Importantly, looking time is also used as a measure of expectation before the outcome occurs, which may or may not violate expectations. Here, the subject's predictions are revealed by where they look. For instance, this method has shown that bottlenose dolphins appear to predict the trajectory of occluded moving objects and the correct location of invisibly displaced objects (Johnson et al. 2015).

### Violation of Object Constancy and Identity

Object constancy is the principle that the features of an object remain constant independently of perception; they do not change their appearance or turn into other objects (i.e., change identity). Typical object permanence tasks ask the subject to choose the correct location of an object, not its correct identity. Nonetheless, a subject that appreciates object permanence should also encode its features and should therefore not expect these features to change when temporarily out of view. This principle is often tested with size constancy, where the size of the target object either remains the same size (possible outcome; Fig. 7b) or is secretly changed (impossible outcome; Fig. 7c). For instance, female dogs looked significantly longer when the size of a ball changed after disappearing compared to it remaining the same, which suggests they relied on size constancy (Müller et al. 2011).

Recognizing the constancy of object identity is tested in a similar matter, except that the object is substituted with a different kind. Rhesus macaques and African gray parrots act surprised and often angry when finding food type A in a location where food type B was hidden and often reject A even though they would eat it immediately under normal circumstances (Pepperberg et al. 1997; Tinklepaugh 1928). Thus, they appear to represent the specific identity of the occluded object and express surprise when its constancy is violated.

### Violation of Object Solidity

Object solidity is the principle that multiple solid objects cannot occupy the same space at the same time. This principle naturally also applies when not directly perceived, such as an out-of-view object colliding with a visible object. Failure to represent this principle may arise from a deficient concept of object permanence in which objects can suddenly disappear or come into existence. The *drawbridge paradigm* is commonly used in this context (Baillargeon 1987; Singer and Henderson 2015). Here, subjects are shown a flat screen that can rotate 180°, from horizontally flat, to vertically upright, to horizontally flat again (Fig. 8). An object is placed behind the screen in such a way that when the screen is rotated 90° (vertically upright), the object is no longer visible for the subject. If the subject understands object permanence, it should know that the object is still present and that when the screen will be rotated further, it should hit the object and thus will not be able to rotate any further (Fig. 8a). In the impossible outcome, the object is secretly removed, and

**Object Permanence, Fig. 7 Violation of object constancy.** (a) The target object (red circle) is hidden behind an occluder. The subject then watches either (b) a possible

outcome, where the target object appears again, or (c) an impossible outcome, where the target object has seemingly changed in size

A) Possible outcome

B) Impossible outcome

**Object Permanence, Fig. 8 Violation of object solidity (drawbridge paradigm).** The screen (blue) rotates away from the subject (looking from the left) toward the object (purple). (a) The  $120^\circ$  rotation is the possible outcome, as

the screen stops at the object. (b) The  $180^\circ$  rotation is the impossible outcome as the screen would have to move through the object (which had been secretly removed). (Adapted from Baillargeon 1987)

the screen fully rotates (Baillargeon 1987; Singer and Henderson 2015). The principle of object solidity prohibits such movements, which should surprise subjects that represent this principle when observing this seemingly impossible outcome (Fig. 8b). Surprise is again measured by increased looking time compared to the possible outcome. For instance, California sea lions and bottlenose dolphins look longer at the impossible event, just like human children, which suggests they have a concept of object solidity (Singer and Henderson 2015). Action-based versions involve a reward that is hidden out of view under one of two rigid boards. Reasoning about object solidity should lead a subject to choose the inclined board because the solidity of both the reward and board causes the inclination, and the reward cannot occupy the same space under a flat board. Some species have passed this test, but care should be taken to control for alternative explanations (Cacchione and Rakoczy 2017) and additional cognitive requirements, such as reasoning by exclusion (Klerk and Jacobs 2021).

Overall, these three VoE paradigms can test for different principles of object permanence (continuity, consistency, and solidity). They have been used to great success for investigating the object cognition of young infants and are promising yet underutilized tools in animal cognition.

## Conclusion

Object permanence is a cognitive skill that has been extensively investigated in humans and

other animals. The study of object permanence in animals builds on the foundational work of Piaget, who formulated a stepwise progression in the first years of a child's development. Although cognitive development is not frequently studied in animals, the six-stage Piagetian framework proved useful in documenting and comparing the highest stage that various species reach as adults. Through this comparison, we gain insight into the adaptive benefits of object permanence and its evolutionary history. However, the reliability of many results is heavily debated, which obscures the comparative power of this paradigm despite its widespread use. Therefore, conceptual clarifications are formulated, and methodological improvements are tested, with the resulting recommendations largely deviating from the Piagetian framework. Crucially, these changes in methodology should suit the species under investigation and aim to limit the effects of confounding factors and alternative explanations; the risks of false positives and false negatives form a trade-off that needs to be carefully navigated. Thus, the unique position of object permanence as a key cognitive ability has – with further conceptual and methodological development – a promising future after its long history.

### Synonyms

#### Object-choice task

The object-choice test (OCT) refers to a family of procedures used to examine nonhuman perceptual and cognitive abilities, in which animals are presented with objects from among which they select one. Correct choices are typically followed by food reward, and in order to make a correct

choice, the animal might be required to discriminate among different colors, remember which object contains hidden food, or properly respond to a communicative signal.

Early studies using the OCT (for review, see Tinklepaugh 1928; Yerkes and Yerkes 1929) examined whether monkeys (*Macaca mulatta*) or children could select the rewarding object based on its position among similar objects. Other studies with raccoons (*Procyon lotor*), for example, presented six differently colored cans to see if the animals distinguished colors; only one color was rewarded, and the animals were given repeated exposure to the variably arranged cans to see whether they could learn to select a particular color. Such OCTs transformed in diverse ways, remaining useful for psychological tests with animals. For example, after a gorilla (*Gorilla beringei*) and chimpanzees (*Pan troglodytes*) observed food being placed in one of four boxes, they selected the correct box after delays of up to 3 h (and could also remember where food was buried when tested 48 h later).

Further memory tests examined the influence of the number of containers from which the animal had to select, indicating that memory diminished as the number of containers increased; some animals (raccoons; dogs, *Canis familiaris*; primates) were able to accurately select the correct container after delay even though they did not maintain perceptual directedness toward that container, although primates showed the longest memories (see Tinklepaugh 1928). Tinklepaugh examined not only how long primates could delay before selecting the correct container but also the positioning of the containers (e.g., one in front of the other, rather than equidistant) and whether primates would be surprised when, upon selecting the correct container, they discovered a food item of lesser value (lettuce) than the one they had seen being baited under that container (banana); they were. Recent variants of these original OCTs include one study in which a bottlenose dolphin (*Tursiops truncatus*) was presented with (usually) 2–3 items associated with 0–6 fish that were presented sequentially after the dolphin selected an item. The dolphin accurately distinguished all possible pairings except that indicating 5 and

6 fish (Mitchell et al. 1985). Another variant found in studies of numerical competence in chimpanzees required the animals to select a container holding a number of items matching the number of stimuli in a previously presented container, or corresponding to an Arabic numeral (see review in Boysen and Hallberg 2000).

OCTs became standardized for use with primates in the Wisconsin General Test Apparatus (WGTA; Harlow 1949). The WGTA separated animals from objects by a screen and required them to reach through the screen to touch an object. Harlow and others used the WGTA to assess the development of learning sets in diverse primate species. Tests included selecting, from among two or more items, the previously rewarded item or the right- or leftmost item, alternately selecting the left then right then left (etc.) item, selecting the previously unrewarded item on the second trial or later sessions (reversal learning), selecting the object that matched a previously observed object, and selecting the odd item from among three items (odddity learning). In some tests, the objects used were food items themselves, evaluating primates' skill at distinguishing the relative number or size (Menzel and Draper 1965). Menzel and Draper (1965) also manipulated whether both food items were visible or one known food item was hidden and the other visible, the latter resulting in only slightly diminished performance compared to the former. The WGTA was later modified for use with nonprimates. The OCT has been used to test hypotheses about the evolution of cognitive abilities (e.g., Harlow's theories about the evolution of learning sets) and, more recently, the evolution of sociocognitive abilities. Work on canids has employed the OCT to test for the roles of domestication and rearing history on the social behavior of dogs.

OCTs have examined animals' comprehension of human communicative cues and animals' behavior to influence human selections, and these are the focus of the rest of this entry. During the task, subjects use a human-facilitated social cue to find a food reward hidden in two or more containers, or humans interpret animals' gestures toward objects to decide which container has food

hidden in it. Manual pointing is among the most common cues used in the OCT; other cues include eye gaze and/or touching or placing markers on the "baited" container. Figure 1 presents a standard comprehension test; if the placement of the dog and human were reversed, it would present a standard production test, where the dog "produces" some indication of which object it chooses. Here we discuss some of the different versions of the OCT used in studies of communication and review the diversity of species examined and some hypotheses that have been tested using the procedure.

**Object-Choice Test, Fig. 1** The object-choice test is often used in studies of comprehension of human social cues. The experimenter provides a cue such as manual pointing toward (typically) the container that has food hidden within it. The subject is then given a chance to make a response, such as approaching the baited container, in order to receive the reward. (Drawing by Lyra Skopos)

## Methodological Variations in the Object-Choice Task

The OCT as a tool for studying communication is implemented in a variety of ways, with variations typically based on the hypotheses of interest, shaping and training procedures needed, and the range of perceptual and social behaviors of species tested. The commonality across most studies is that, for experimental trials, an object, typically food, is placed inside of one of two (or more) opaque containers (and thereby hidden). Then an experimenter provides a communicative signal to the animal or awaits a communicative signal from the animal, which indicates the location of the food.

Familiarization with the procedure is typically conducted prior to training and might consist of simply showing the subjects that one of two or more containers contains food and requiring some kind of indicating act by the subject (e.g., approaching, pointing, begging gesture) in order to receive the food. Following this procedure, positional, gestural, and eye-gaze cues become the only sources of information the subjects can use to determine which of the containers is baited. The containers are usually visually but not tactilely accessible during the cueing phases of the procedure, and correct choices are rewarded by offering the food reward to the subject, releasing the subject to retrieve the food, or moving the chosen container into the animal's enclosure. In studies of deception, however, if the animal selects or indicates correctly, the cooperative participant gives the animal the food, but the competitive (deceptive) participant keeps the food. With a competitive participant, the animal has to learn to indicate the unbaited container or select the container the participant does not point to in order to get the food.

Task difficulty may vary by the level of cue salience, such as having the indicating individual touching the container or briefly glancing at it, or in terms of memory required to make a selection, via the delay between signaling and opportunity to make a choice. Pointing gestures may take many different forms in terms of the distance between the experimenter and the objects, the

duration of the point, and the lateral dimension of the point (e.g., cross-body vs ipsilateral). Since eye-gaze changes typically accompany pointing gestures, the experimenter may look in the same direction of the point. Conditions, or entire studies, may involve eye gaze alone as a cue for which container is baited. The following descriptions are based on standard usage of terminology from the literature, especially Miklósi and Soproni (2006).

**Proximal and distal pointing.** In the proximal pointing condition of the OCT, containers are placed between the subject and the experimenter, and both are within reach of the latter. In the distal condition, the subject and experimenter also typically face each other, but the containers are separated by a greater distance. Miklósi and Soproni (2006) consider 10–40 cm spacing between point and container to be proximal and 50 cm and greater to be distal.

**Static, dynamic, and momentary pointing.** The duration of the pointing gesture can vary in duration and, relatedly, complexity. A point is already present when the animal first sees the pointer in static pointing, whereas the point is initiated while the animal observes the pointer in dynamic pointing; in both cases, the point continues until the animal makes a choice. Momentary pointing consists of pointing briefly (a couple of seconds) at the object before returning the arm to the side of the body. Unlike static or dynamic pointing, momentary pointing requires that the subject remember the location indicated.

**Flexibility of pointing.** The range of complexity of animal responses to pointing cues has been tested using points that are relatively ambiguous in comparison to those previously described. Pointing with the foot or elbow or with an arm and finger extended across the body toward a baited container on the contralateral side increases the complexity of the task. Another level of difficulty can be introduced by using asymmetric pointing, where the experimenter stands adjacent to the empty container and points toward to the baited one.

**Tap, touch, or mark.** The use of a touching or tapping cue involves local or stimulus enhancement, or the direct drawing of the subject's attention to a stimulus by physical contact. This might

be done to test whether local or stimulus enhancement accounts for selecting the baited container. A less direct option is placing an iconic cue (a photo or replica) or physical marker on or near the baited container in order to draw attention to it.

**Auditory cues.** The OCT is also used to test whether animals use auditory cues as a source of information about food location. For example, Rossano et al. (2014) showed that dogs respond to the direction in which a human speaks to make their choice.

**Eye gaze.** The OCT has been used in studies exclusively examining gaze sensitivity or studies examining multiple types of social cues that include eye-gaze direction. Gaze following, namely, using eye direction, could represent the capacity for understanding another's visual perspective.

What may seem like minor variations in methodology can elicit very different results (Miklósi and Soproni 2006). Thus, the methodology used must be carefully examined before any comparisons among species, ages, or other variables of interest are drawn. One of the most appealing elements of the OCT is its versatility and flexibility; small adjustments to the methodology open the opportunity to explore the gesture-following abilities of myriad species. Success on more complex variations of the OCT may be taken as evidence that the visual attention and gestural signals provided by humans were understood by the animals. We review a sampling of the various species tested and results from some of this work (for a complete inventory and citation list of species tested so far, as well as all uncited references, see Krause et al. 2018).

## Review of Species Tested

**Primates.** Chimpanzees; bonobos, *Pan paniscus*; gorillas, *Gorilla gorilla*; orangutans, *Pongo pygmaeus*; and a gibbon, *Hylobates lar*, have all shown evidence of comprehending human gestures in the OCT, but there are numerous sources of variation that could account for individual, task-related, and possible species-level differences in

performance. For example, chimpanzees, bonobos, and orangutans that have had extensive contact with humans, including learning an artificial or gestural language system, outperform nursery-reared, mother-reared, and/or wild-caught apes on the OCT (e.g., Lyn 2010). Results are ambiguous with regard to gorillas on the OCT, where fewer studies have been conducted.

The apparent difficulty that some chimpanzees and other apes have with pointing using the OCT has generated much discussion and debate in comparative psychology. It seems puzzling that chimpanzees, the closest living relative to humans, are outperformed in the OCT by domestic dogs. The role of domestication in canine cognition has been offered as an explanation (Kirchhofer et al. 2012), though there is by no means consensus on this issue (Leavens et al. 2017). After all, dogs with extensive human contact (pets) outperform dogs with less contact, such as those reared in kennels (D'Aniello et al. 2017), and apes with extensive experience interacting with humans likewise outperform apes with less human interaction (Lyn 2010). Also, the types of cues used in the OCT influence performance (Miklósi and Soproni 2006). If we measure performance using only the proximal pointing variation, then chimpanzees might be regarded as relatively poor at understanding human pointing. However, when tested with distal pointing, rather than proximal pointing, chimpanzee (and bonobo) performance exceeds chance levels (Lyn 2010). Why might this be? Food containers are high-interest objects to chimpanzees, and because both containers and social cues occupy the same visual space, the pointing and gaze cues must compete with the more salient and immediately interesting containers (the “distraction hypothesis”). The distal (“peripheral”) condition puts human experimenter and containers in a different visual space and in addition creates a situation in which an incorrect choice comes at a greater cost than the proximal (“central”) condition (e.g., latency between making a choice and receiving feedback is longer in the distal condition: see Mulcahy and Hedge 2012 for discussion). Interestingly, dogs performed better in the distal than the proximal condition (with performances similar to those of apes in the two

conditions in the Mulcahy and Hedge study), whereas cats (*Felis catus*) performed well in both conditions (comparable to dogs in the distal condition), though fatigue may have been a factor as dogs were tested on 1 day and cats across 2 days (Kraus et al. 2014). The authors suggest that cats are highly responsive to the movement involved in the pointing gesture in making their selection, whereas the dogs (like apes) may have been distracted by the closeness of the food bowls in the proximal condition.

Tests with iconic cues (photographs or replicas of food or containers) have been examined with apes (Herrmann et al. 2006). In this study, the authors in experiment 1 varied whether or not the apes saw the placement of the iconic image atop the container. Some of the 27 apes (including chimpanzees, gorillas, orangutans, and bonobos) performed at above chance levels when they saw (or when they did not see) the placement of the replica, others when they saw (or when they did not see) the placement of the photograph, and others when they either saw or did not see the placement of the replica (or the photograph); one ape (a bonobo) succeeded in all four conditions. Most apes failed to succeed under all four conditions, although on average the apes succeeded on all conditions except the one with the replica they had not seen being placed atop the container. (Note that, throughout this study, the authors mistakenly examined chance occurrence for individual subjects using a two-tailed binomial test; in fact, they should be using a one-tailed binomial test, a remarkably consistent error among this research group when testing apes, but not when testing dogs [see Mitchell et al. 2018, Appendix].) Similar findings occurred in experiment 2 when, testing 11 of the best performers, each container had a photo or replica of a (different) fruit atop them, or one container had a photo or replica of a fruit and the other had a photo or replica of a non-fruit on top, but one of the two iconic items was of the fruit the ape had seen before it was hidden (but in this case, a gorilla succeeded at above chance levels on all four conditions and was the only ape to succeed when fruit replicas were on top of both containers). Average performance was above chance for all conditions except the one with two

fruit replicas. The same apes (experiment 3) were then shown a photo of one of two containers which had been baited and were then provided with both containers; following two sessions of this, the same apes (experiment 4) were shown that one of two transparent containers containing different fruit was locked and were then shown a photo of the fruit in the unlocked box. In both experiments, all apes failed on the first session, and all failed on the second session except for one gorilla (the same one who had succeeded in experiment 2). (Note that the authors mistakenly depict the greater than chance performance of 13 out of 18 that the gorilla obtained in the second session in each of these final experiments as chance performance.) The data from this study indicate that some apes can use iconic cues to pick the correct container in OCTs but that with more things to remember for success, performance diminishes: a standard finding in tests of working memory.

At least ten monkey species have been tested using the OCT (see Krause et al. 2018), including capuchin monkeys, *Cebus (Sapajus) apella*, which reliably followed pointing and eye-gaze plus pointing cues toward baited containers but did not reliably use gaze cues alone. However, capuchin monkeys could learn to use gaze direction in the OCT through extensive training, but it is likely that head orientation, and not eye direction per se, was the salient feature used by the monkeys to determine the food location.

As with apes, performance on the OCT among monkeys is widely variable and dependent upon training, rearing histories, and procedural variation. For example, long-tailed macaques (*Macaca fascicularis*) reliably use proximal pointing cues, but not distal ones, to locate food in the OCT (Schmitt et al. 2014), which contrasts with what tends to occur with chimpanzees. The experimental trials included conditions in which the experimenter stood behind a curtain and reached out with only their arm, a doll arm, or even a stick to indicate the baited container. Interestingly, the monkeys performed best under conditions where the experimenter's face was blocked by a curtain, even if an inanimate object was used to indicate the baited container. Schmitt et al. (2014) suggest that face-to-face contact in a feeding context could

be interpreted as threatening by monkeys (as it may be with other species, including apes) and that removing this variable and introducing the most salient cue (outstretched arm or object) remove what would be a confounding variable if one wants to make meaningful comparisons with other species, including ones that may respond defensively to direct eye contact. As tempting and fascinating as species comparisons may be with the OCT, any interspecific differences found do not default to a sound, phylogenetic interpretation (see Leavens et al. 2017).

A naturalistic variant of the OCT examining chimpanzees' responses to a conspecific's knowledge of the locations of varying amounts of hidden and visible food was created by Menzel (1974). A chimpanzee was shown the location of the hidden food in a one-acre field and then was allowed into the field with conspecific comrades, all of whom saw an available piece of fruit. The knowledgeable chimpanzee usually led the group to the hidden food, which was shared by all. However, one chimpanzee became greedy, maintaining all the food for himself, and the knowledgeable chimpanzee attempted to avoid indicating the location of the hidden food for this chimpanzee. In addition, when there were two caches of food, one smaller than the other, the knowledgeable chimpanzee led the greedy chimpanzee to the smaller cache of hidden food, before herself going to the larger cache (a form of deception). The follower chimpanzee picked up on these maneuvers, creating distress for the knowledgeable chimpanzee. Similar "informed animal" studies involving mangabeys, *Cercocebus torquatus torquatus* (Coussi-Korbel 1994), and Tonkean macaques, *Macaca tonkeana* (Ducoing and Theierry 2003), showed similar findings.

Menzel's work led Woodruff and Premack (1979) to control more variables by using the OCT with chimpanzees and by having humans act as either cooperators or competitors (as described earlier). Each chimpanzee was presented with two containers, one of which was baited. If the chimpanzee knew which was baited and a human approached the containers who did not know which was baited (the production context), the chimpanzee needed to indicate the baited

container for the cooperator (who gave the food to the chimpanzee) and withhold information as to which was baited or indicate the unbaited container for the competitor (who kept the food). If the chimpanzee did not know which container was baited and a human who (the chimpanzee knew) knew which was baited approached the containers (the comprehension context), the chimpanzee needed to select the container the cooperator indicated and select the container other than the one the competitor indicated. Chimpanzees used a variety of methods of indicating a container, including combinations of frontal position toward the container, gaze from container to person, and whole arm or leg pointing; humans mirrored chimpanzee responses in the comprehension context, using similar positional, gaze, and whole arm or leg pointing. Chimpanzees eventually succeeded, after 100 or so trials, in generally acting appropriately in both production (indicating the appropriate container to get the food) and comprehension contexts (indicating the appropriate container to get the food or withholding information from the competitor, for which they were rewarded). Minor variations on the production version of this general experimental form were used with brown capuchin monkeys, *Cebus apella* (Mitchell and Anderson 1997); squirrel monkeys, *Saimiri sciureus* (Anderson et al. 2001); brown lemurs, *Eulemur fulvus* (Genty and Roeder 2006); and black lemurs, *Eulemur macaco* (Genty et al. 2008), with similar results. Some of the primates withheld information from the competitor, even when they were not rewarded for this withholding (Genty et al. 2008). Another variation employed both an informed animal and an OCT, where both a dominant and a submissive Tonkean monkey saw food atop a container, but only the submissive knew where hidden food was (Canteloup et al. 2017).

**Canids.** The OCT has been very popular among those studying canine social cognition. Domestic dogs are by far the most common species in studies using the OCT and comparative studies employing captive populations of wolves (*Canis lupus*), foxes (*Vulpes vulpes*), dingoes (*Canis dingo*), and coyotes (*Canis latrans*).

Since Miklósi et al.'s (1998) study using the OCT with dogs, dozens have followed. In fact, over 50 papers have examined pointing comprehension in over 2000 dogs (Krause et al. 2018). It was apes' skill at understanding pointing, and monkeys' lack of skill, that initially spurred Miklósi et al. (1998) to use the OCT to examine dogs' understanding of human pointing, which they viewed as comparable to that of apes. Researchers who believed that apes showed limitations in their responses to human pointing to find hidden objects were particularly intrigued by dogs' apparently immediate understanding of human points (Hare and Tomasello 1999), creating a view of ape inadequacy and dog skill in relation to human pointing (e.g., Kirchofer et al. 2012) that has been questioned on several fronts, particularly by presenting evidence of ape skill (Leavens et al. 2017) and dog inadequacy (D'Aniello et al. 2017; Udell et al. 2008).

In general, pet dogs respond appropriately to pointing in the OCT. Factors which influence dogs to respond inappropriately to human pointing in the OCT include side preferences, earlier reinforcements, early experience with little to no human interaction, and knowledge of the location of the reward (D'Aniello et al. 2017; Petter et al. 2009; Udell et al. 2008). For example, when dogs knew by sight which one of two containers was baited in the OCT, they were more likely to choose the baited container even if the human pointed to the other container than if they did not know which container was baited (Scheider et al. 2013); however, when their knowledge of which container was baited was based on smell, they tended to follow points to the empty container (Szetei et al. 2003). Human-raised wolves selected the baited one of two bowls based on human gestures in several studies, though the data conflict somewhat: wolves selected the baited bowl when a human touched or pointed proximally to it, but not when the human pointed distally to it (Miklósi et al. 2003; Virányi et al. 2008); and human-socialized wolves selected the baited bowl when the human momentarily pointed distally to it and did so either with no apparent training as adults (Udell et al. 2008) or only after extensive training as pups (Virányi et al. 2008).

There is great variability across wolves and dogs in their responsiveness to human social cues in the OCT.

Canids have also been used in replications of the Woodruff and Premack (1979) deception studies. Studies of deceptive pointing (and of extinction of responding to pointing toward the unbaited container) in standard OCTs examine dogs' responses to pointing when the dogs did not know under which object the food was hidden. Dogs generally selected one of two containers pointed to regardless of whether the pointer was cooperative or competitive. However, the dogs sometimes refused to respond or selected the other container, more often with the competitor than the cooperator (Petter et al. 2009). It requires many trials for dogs to avoid responding to pointing by a deceiver (Petter et al. 2009). Dogs respond to artificial human hands pointing toward or away from transparent containers to decide which to choose; surprisingly, when an artificial hand pointed toward an empty transparent container, and another artificial hand pointed away from a baited transparent container, most dogs selected the unbaited container that the artificial hand pointed to (Kundey et al. 2014).

Canids communicate differently depending on whether the human is cooperative or communicative. Following extensive experience with a human indicating cooperatively and competitively (the comprehension context), dogs were put into a production context, such that the dog now indicated which bowl a human should choose (Petter et al. 2009). Dogs usually indicated the baited bowl and sometimes the unbaited bowl or withheld information, for both the cooperator and competitor. In these studies, the standard OCT was used, but with the dog and human in Fig. 1 in reversed positions. To determine if dogs could learn to trust cooperators and avoid competitors through brief exposure to each, researchers gave dogs direct experience with a cooperative and a competitive human, by having each human independently lead the dog to two containers where the dog knew which container was baited and then either giving the dog the food (cooperator) or keeping the food for herself (competitor) when the dog indicated the baited bowl. Later, the

dogs were allowed to lead the cooperator or the competitor separately to one of three boxes: one containing a preferred food, one containing a less preferred food, and one empty (Heberlein et al. 2017). Over (usually) four trials each with each person, most of the dogs led the cooperator to the box containing the preferred food most of the time, and most led the competitor to the box containing the less preferred food or the empty box most of the time. In a similarly organized study with wolves and dogs (Heberlein et al. 2016), only one of the three boxes was baited with (a preferred) food, and the cooperator or competitor observed the canid when in a room with the three boxes and decided which box the animal selected. Both wolves and dogs exhibited almost identical frequencies of directing attention to the box containing the food and did so much more frequently for the cooperator than for the competitor.

Dogs are also attuned to nonsocial signals of a container's being baited or unbaited, analogous to social signals of cooperativeness and competitiveness, respectively. Petter et al. (2009) used either a black or white box as a marker to indicate that one of the containers near a box was baited or empty (for some dogs, white indicated the baited container and black, the empty one; for others, it was the reverse), thereby mimicking the cooperator/competitor context without a human present. Dogs responded appropriately to the markers, more often selecting a container when its box indicated it was baited and selecting the other container when a container's box indicated it was empty.

Whereas the domestication hypothesis of Hare et al. (2010) posits that dogs, as a result of domestication, are inherently appropriately responsive to human pointing (and other social signals) even without any exposure to humans prior to the pointing, an alternative hypothesis focusing on dogs' socialization by humans, the two-stage hypothesis, implicates dog's social interaction with humans and subsequent conditioning as necessary for appropriate responses to pointing (Udell et al. 2010). The evidence so far appears not to support the domestication hypothesis. Although domestication may provide dogs with

some predispositions necessary to understand pointing, they are not born with the ability to successfully use human cues. In contrast to pet dogs, research dogs raised in a kennel with limited human socialization experience failed to reliably use distal and proximal pointing to locate a hidden reward (D'Aniello et al. 2017). Free-ranging dogs in India were more likely not to follow points than to follow them in OCTs, with most (35%) juveniles and adults failing to follow and most (69%) pups following points (Bhattacharjee et al. 2017), suggesting that dogs may unlearn their responsiveness to pointing as they mature based on their experiences of humans. Thus, rearing history and early experience with humans are critical to the development of pointing skill in any individual dog, lending support to the two-stage hypothesis. Tamed dingoes (a type of dog which had been domesticated, had gone wild, but is often tamed as a pet) on average selected the baited of two containers following a variety of human indications, including diverse points, showing chance performance only when the human stood by one container but pointed to the other. Note that dogs who respond appropriately to human pointing will sometimes actually ignore such pointing (e.g., during play with a human; Mitchell et al. 2018), and the same may occur during OCTs.

Specific examples of human contact that may contribute to the development of a dog's (or wolf's) ability to follow pointing gestures include treat offering, filling food bowls, toy throwing and playing, or informal pointing to objects to direct the animal's attention in a daily context. Each of these interactions, intentional or not, exposes the animal to stimulus-response-consequence situations that increase the likelihood of repeating the corresponding behavior, such as following human hands in response to a pointing stimulus, reinforced in the past with food or toys, toward a new location or object (Miklósi et al. 2003; Udell et al. 2010). Canine choice performance is significantly influenced by ostensive communication with humans, such as calling the dog's name (e.g., Erdőhegyi et al. 2007).

An experimental study of domesticated and non-domesticated foxes interpreted as supporting the domestication hypothesis (Hare et al. 2005)

provides findings more consistent with the two-stage hypothesis (developed 5 years after the study). Domesticated foxes had been selected for breeding based on friendliness to humans, whereas non-domesticated foxes (which expressed fear and aggression toward humans) had not. Domesticated foxes and age-matched dog puppies, both presumably familiar with humans, used a human's pointing and gazing at one of two containers to select the baited one at levels greater than chance (on average, just over 15 out of 18 trials). However, non-domesticated foxes also used the human's pointing and gazing to select the baited container at levels greater than chance (on average, 12 out of 18 trials). Although the domesticated foxes used the point and gaze gestures more frequently than non-domesticated foxes did, it is surprising, if the domestication hypothesis is true, that the non-domesticated foxes followed the gestures at greater than chance levels. The methods indicate that the non-domesticated foxes experienced "weeks of exposure to humans" prior to the point and gaze study (p. 228), thereby indicating some human socialization, and, oddly, the non-domesticated foxes had interacted with the experimenter "for twice as long as the [domesticated] foxes" (p. 229), who had "far less experience with humans" than the non-domesticated foxes (p. 228), thereby increasing the chances of conditioning (p. 228). By contrast with the foxes, domestication shows a much more clear-cut beneficial effect on ferrets (see below).

**Other domesticated animals.** Inspired by the possibility that domestication has influenced social behavior in dogs, investigators have used the OCT to test whether other domesticated species understand human social cues. Pet cats showed skills comparable to that of dogs in responses to human momentary and dynamic distal and proximal pointing in OCTs and better than that of dogs in responses to momentary proximal pointing (Kraus et al. 2014). Pigs (*Sus scrofa domestica*) can spontaneously use proximal and, to some extent, distal pointing in the OCT. Goats (*Capra hircus*) can use touching and, to varying degrees, pointing and gaze cues during the OCT. Also, horses (*Equus ferus caballus*)

learn to follow even momentary distal points, particularly if they have extensive experience in communicative contexts with humans prior to the beginning of the experiment. The learning required by horses that had or lacked extensive exposure to human cues does not lend support to the domestication hypothesis.

A comparison of domestic ferrets (*Mustela furo*) and wild x domestic tamed *Mustela* hybrids in OCTs seems to offer support for the domestication hypothesis (Hernádi et al. 2012). Domestic ferrets (*Mustela furo*) were comparable to dogs in their ability to follow momentary pointing to or sustained touching of a container in OCTs, whereas the diverse set of *Mustela* hybrids performed at chance levels in relation to the pointing or touching to locate hidden food. However, the hybrids (unlike the domestic ferrets) avoided direct eye contact with their human owner, and the authors suggest that failure to engage in eye contact with familiar (and other) humans is the basis for animals' failure in pointing tasks. Thus, rather than domestication leading directly to understanding of human social signals, it may allow for tolerance of and/or preference for eye contact with humans, which is necessary for the development of understanding of human social signals (Miklósi et al. 2003). The two-stage hypothesis, linking animals' social interaction with humans and learning about human social signals to explain success on pointing and other OCTs, also seems insufficient, as the hybrids were extensively socialized with their owner.

**Non-domesticated species, tamed individuals.** Some studies have examined comprehension of pointing using the OCT with tame individuals of non-domesticated species. Bottlenose dolphins selected the appropriate object when points were stationary and dynamic proximal points and when points were direct or cross-body; some were also successful when stationary and dynamic eye gaze indicated the object to choose. None were initially successful at understanding that a same-sized "replica" of one of the two objects indicated which of the objects to choose, but two became successful after brief training. Similarly, South African fur seals (*Arctocephalus pusillus*) tested using the OCT

selected appropriately in response to whole arm pointing, eye gaze, both pointing and gaze combined, and cross-body pointing and gaze but did not respond appropriately to finger pointing, short gaze, or presentation of object replicas. Some of the African elephants (*Loxodonta africana*) tested on static as well as momentary direct and cross-body points selected the indicated objects, and one elephant was successful on all four point types. Some elephants later “generalized” their understanding to foot points. Human-reared and tamed megachiropteran bats (*Pteropus* species) successfully followed pointing gestures when they were captive born, but not wild born. As with the ferrets, findings once again suggest that neither domestication nor human rearing is necessarily enough to successfully respond to human pointing. Clark’s nutcrackers (*Nucifraga columbiana*) can use a look-point-touch gesture cue to choose food locations. Interestingly, the birds learned to successfully discriminate between gestures made by experimenters who were either naive or informed about the location of the food. By contrast, ravens (*Corvus corax*) appear to be relatively unresponsive to pointing and gaze cues in the OCT.

## Conclusion

The OCT has a long history in comparative psychology. The task is well-suited for studying perceptual and cognitive capacities among nonhumans. The OCT utilizes the ubiquitous motivation for food reward among animals to engage their attention to the specific experimental manipulations. Also, the OCT generally elicits a clear, overt behavior indicating choice. These are among the properties of the OCT that make it suitable for use with a wide array of species and research questions. Over the past few decades, the OCT has become a standard procedure for examining the capacities that animals have for following human communicative signals. Interestingly, comparative psychologists are often warned to avoid the Clever Hans effect, in which animals only appear to be solving the problems they are given but are instead responding to cues

unwittingly provided by humans. Contemporary research using the OCT is revealing that animals’ skills at reading human social signals, the basis of the Clever Hans effect, are itself worthy of study.

## Objective

► [Goal](#)

## Obligate Trait

Julianne Wilson  
University of Pennsylvania, Philadelphia,  
PA, USA

### Definition

A trait exhibited by a species that persists in all environmental conditions and is necessary for survival.

### Description

When a trait so significantly increases the chances of a species' survival that it becomes a mandatory system, it is considered to be obligate. An obligate trait remains consistent in times of environmental change. Thus, it can not be lost or 'turned off' even if the environment undergoes a rapid change that would seemingly cause the trait to be futile.

Because such a system can be extremely restrictive, the evolution of an obligate trait is

only advantageous if it reduces a consistent opposition faced by a species. The energy exerted to maintain the trait cannot exceed its overall benefit to the species. Therefore, traits considered to be obligating usually effect circumstances that remain predictable throughout the lifetime of the species (Newton 2012). Some commonly observed obligate traits are discussed below.

### Obligate Parasite

An organism is considered to be an obligate parasite if at least one part of its life cycle is unable to proceed without the use of a host. The host may be used as a source of food, environmental protection or hold another function essential to the parasite. All viruses are considered to be obligate parasites because they replicate by invading a host cell (Hogg 2005). Although the survival of the invading virus itself is not directly affected by the host cell, the continuation of the viral species is impossible without such interaction.

### Obligate Aerobe/Anaerobe

Organisms classified as obligate aerobes require oxygen for survival. Exogenous oxygen molecules are used in the respiration pathway of these organisms and is essential for energy production (Hogg 2005). In contrast, obligate anaerobes are unable to survive in the presence of oxygen. These organisms are unable to break down exogenous oxygen, allowing the molecule to form free radicals within the organism and cause extensive cellular damage. Obligate anaerobes also respire, but do so through the use of inorganic electron acceptors such as sulfate or carbon dioxide instead of oxygen (Hogg 2005). An anaerobic lifestyle can be beneficial for organisms living in extreme environments such as deep in soil and within the human digestive system.

### Obligate Mutualism

Species considered to be obligate mutualists consistently engage in one or more mutualistic

relationships for survival and/or reproduction. A mutualistic relationship between two species can be obligate for one or both of the species involved. Mutualistic interactions between species are evolutionarily favorable to both parties but may differ in relation to degree of benefit and relationship dependence (Boucher 1988).

An example of an obligate mutualistic relationship is that of the yucca moth and the yucca plant. Yucca moths pollinate yucca plants, making them necessary for survival. In turn, yucca moths use the flowers of the yucca plants as a home for their eggs and the plants' seeds to nourish their young. Many years of evolutionary events have led this relationship to become obligate, such as the decrease in the amount of yucca plant pollinators. In addition, yucca moths have developed a distinct mouthpiece with which to carry the yucca plants' pollen, making their relationship even more efficient (Pellmyr and Huth 1994). This mutualistic relationship is obligate for both parties, as both the plants and the moths depend on it for survival.

## Observational Conditioning

Thomas R. Zentall

University of Kentucky, Lexington, KY, USA

Observational conditioning refers to the learned association between an environmental action and a desired consequence. An example might be the case of an observing rats that sees a demonstrator press a lever and soon after a pellet is delivered to the demonstrator. What makes this different from imitation is the behavior of the demonstrator may not be necessary for learning to occur. That is, the movement of the lever followed by pellet delivery, a stimulus-stimulus association, may be sufficient to increase the probability that the observer will press the lever (see Heyes 1994).

Observational conditioning is different from social facilitation (facilitation due to the mere presence of the demonstrator; Zajonc 1965), the effect of an increase in the observer's general arousal produced by the presence of the demonstrator (see section on social facilitation). It is also different from stimulus enhancement, attention drawn to the lever by seeing the lever move up and down (see section on stimulus/local enhancement). Observational conditioning can be thought of as a special case of learned affordances (see section on learned affordance). In learning the affordances of a particular context, one may learn that a barrier can be jumped over in order to escape from shock. More closely related to observational conditioning, a child may be given a marking pen with a cap over the felt tip. By

seeing a demonstrator pull the cap off the pen, the child may simply learn the affordances of the pen and cap. She may learn that a pen has a removable cap and there are actually two parts. In principle, one could accomplish the same thing by showing the child a video of the pen and cap moving in opposite directions. By doing that one would not consider it an example of imitation because there would be no one performing, thus nothing to imitate.

In observational conditioning, the affordance of the context consists of the temporal relation between the movement of the lever and the delivery of the pellet. One can think of observational conditioning as a presentation of a conditioned stimulus (the moving lever) followed by presentation of an unconditioned stimulus (the pellet or more specifically the sight and sound of the pellet). Thus, observational conditioning actually involves higher-order conditioning. It assumes that there is already conditioning between the sight and sound of the pellet appearing at the feeder and the unconditioned effect of consuming the pellet.

Perhaps the strongest case for observational conditioning can be found in fear conditioning (Mineka and Cook 1988). Laboratory raised rhesus monkeys are not naturally afraid of snakes but if they observe another monkey react fearfully to a snake, they will also react fearfully to the snake. But clearly there is a predisposition to acquire this fear because if the other monkey appears to react fearfully to a flower (the demonstrator is exposed to a snake but the observer sees only the flower) a fear reaction to the flower does not develop.

Observational conditioning should not be confused with observational learning. Observational learning has sometimes been used interchangeably with imitation (see e.g., Galef 1988), but at other times it has referred to deferred imitation. That is, imitation in which some time elapses between the period of performance by the observer and the period of observation (see Bandura 1977). Bandura's view is that imitation that occurs at the same time as observation may involve some kind of reflexive response (what Byrne 1994 calls response facilitation) but

observational learning requires an internal representation of the observed behavior that is recovered at a later time to be performed by the observer (see Dorrance and Zentall 2001).

## Introduction

Animal behavior is studied for many different reasons, and observations can take place in a variety of settings. The way one chooses to study animal behavior either in a laboratory, at a zoo, or in the wild depends on the research

question being asked. Questions often begin broadly and become more specific after preliminary observations. Once the research question is formulated, it is necessary to identify the behaviors that will be measured. For example, if the question is asking if males of a group are more aggressive than females, it is necessary to determine which behaviors will be defined as aggressive and how these behaviors will be observed and recorded. An ethogram is a comprehensive inventory with the purpose of providing a description of all behaviors known to exist in a particular species. A researcher can use this to determine which behaviors are appropriate for analysis in a study. A limited ethogram that only includes behaviors relevant to the current study may also be created.

## Events and States

Behaviors can be measured on a continuum from events to states. While all behaviors realistically require some amount of time to complete, behaviors can be categorized for observation based on their duration. Events are discrete behavior patterns that occur in a relatively short amount of time. Event behaviors are measured by the count, or number, of occurrences of the behavior. For example, each time a horse displays a foot-stomping behavior, it can be counted as an event. On the opposite end of the continuum, states are behavior patterns of relatively long duration or are prolonged activities. States are measured by the duration of the behavior. For example, the amount of time a horse spends sleeping can be a measure of state.

Since events and states are on a continuum, a researcher can choose to describe many behaviors as either events or states. The choice to define a behavior as an event or a state is at the discretion of the researcher and is based on the research question they are attempting to answer. A researcher addressing the number of times an individual engages in a specific behavior may define it as an event. In contrast, a researcher investigating the amount of time an individual engages in a specific behavior may frame the same behavior as a state. For example, a

researcher could count the number of times a lion is observed lying down if they were investigating the frequency of resting behaviors. These frequencies are obtained by counting the number of times a behavior or activity is initiated. Alternatively, the researcher could record the amount of time the lion spends lying down in order to investigate the duration of resting behaviors. The decision to define behaviors as either events or states should be given careful consideration based on the question of interest. Defining a behavior as an event not only is determined by the type of research question, but it also affects which method of observation should be used when observing and recording the behavior.

## Rates and Frequency

When events are being scored, the simplest way to quantify the results is by tallying the number of occurrences of a specific behavior. For example, a researcher may tally the number of times an individual performs a grooming behavior. Although the resulting count is informative, it does not provide results that are appropriate for comparisons, analyses, or conclusions. Describing the count per unit time produces a more meaningful metric. Rate (or frequency) is defined as the number of occurrences of a behavior per standard unit of time (e.g., per minute, per 5 min, per hour, or per day). Rate and frequency are synonymous terms of behavioral measurement that allow researchers to compare within and across experiments and provide useful information that count alone does not reveal. Rate is calculated by dividing the number of occurrences of a behavior by the unit of time. For example, a chimpanzee who has three occurrences of grooming in 10 min during the first observation and has one occurrence of grooming in 10 min during the second observation has response rates of 0.30 and 0.10 per minute.

In the previous example, a 10-min observation time is used for both observation periods. Ideally, observation times would be equal for each individual or group in the study, allowing for easy comparison due to the standard unit of time.

In many situations, however, an animal may not be visible to the researcher during the entire observation period. Rates also allow researchers to compare counts from observation periods of different lengths. Unequal observation times that are beyond the researcher's control can occur when an animal changes location to an area secluded from the researcher's view. For example, a chimpanzee who has five occurrences of grooming in 10 min during the first observation and has three occurrences of grooming in 8 min during the second observation has response rates of 0.50 and 0.38 per minute.

## Sampling Rules

In order to design a viable study, researchers need to engage in the systematic observation of behaviors. There are two components of recording methods that a researcher should examine when designing a research study. First, the sampling rules should be considered. Sampling rules dictate which subject or subjects should be watched and when their behavior(s) should be recorded. The second design consideration is the recording rules, which dictates how the behaviors should be recorded.

There are four widely used sampling rules: focal animal, focal behavior, scan, and ad libitum. Researchers must determine if a single animal, a subgroup, the whole group, or a specific behavior should be observed.

Focal animal sampling is a technique in which the observer records all instances of behavior of a previously selected individual for a specific period of time. The behaviors displayed by the other members of the group are not recorded. This sampling technique provides a flexible platform where solitary and social behaviors involving the focal animal can be recorded. The focal animal can be recorded as the actor or receiver of a behavior based on the study questions and ethogram. Generally, the activities of a single animal are recorded for a predetermined period of time, and then the observer moves to watch the next animal. This is repeated until all of the animals in the group or subgroup are observed. If

possible, focal animals should be selected for observation in a randomized order.

Focal behavior sampling is a technique in which all instances of a specific behavior displayed by any member of the group are recorded. This sampling rule is an effective recording method when the study question pertains to a specific scenario or when the behavior of interest is rarely exhibited. Within focal behavior sampling, a researcher may choose to only record the specific behavior of interest, or they may record both the focal behavior and the sequence of behaviors (displayed by the original actor or behaviors of others in response) that follow the focal behavior as well. For example, a researcher studying the use of aggressive kicking in African elephants may record only instances of forward or sideways foot thrusting in the direction of another elephant. This threat display by any individual in the group would be noted. Any of the chosen responding behaviors defined in the ethogram by the researcher may also be recorded.

Scan sampling is a sampling technique in which the observer surveys an entire group of animals at a single point in time to record the behavior of each individual and repeats the process at defined intervals. This sampling technique provides a representation of the overall distribution of behaviors and the behavioral repertoires of the group simultaneously. Ideally, scan samples are collected in such a rapid fashion that they represent a single snapshot or moment in time. Practically, without the ability to freeze frame live action, it takes a certain amount of time to record the data. The interval between scans should be substantial enough to record accurate observations before the next scan time point arrives. Scan data can be used to generate estimates of percentages of time engaged in different activities. This method can also be used to compare the behavioral patterns of one group (which can be based on social cohort, age, sex, etc.) to the behaviors of another group. Unlike focal behavior and focal animal sampling, scan sampling requires the use of the instantaneous recording rule (see below) to record behavior because behavior is only being observed instantaneously (at the single point of the scan). In this instance, a researcher

may be interested in evaluating the differences in behavior patterns between three male adolescent giraffes and three female adolescent giraffes. The observer may sample the behavior of the giraffes every 20 s for a 5-min period several times a day. After accumulating enough data, the researcher can compare the activities of adolescent male and female giraffes.

Ad libitum sampling is a sampling technique in which there are no systematic conditions placed on the behaviors of individuals/groups being recorded or a specific time interval in which the recording is completed. In this method, which is similar to note taking, the observer records behavior based on what is interesting or pertinent. Ad libitum sampling is prone to observer bias largely because the activities of interest tend to be charismatic and gregarious in nature. Mundane behaviors are easily overlooked despite their potential to be influential. For example, one way a chimpanzee may invite another to reconciliation after a recent conflict is by making eye contact (De Waal 2005). Because subtle yet important behaviors, such as brief eye contact, can be disregarded by an observer during ad libitum sampling, it is generally not suggested for use in scientific studies. Another potential issue with this sampling technique that must be addressed are discrepancies in how each behavior is described. As there are no behavioral definitions characterized prior to the observation, differences in how behaviors are categorized and detailed may arise throughout sampling. Despite these limitations, this sampling technique can still be used effectively when the study goal is to collect contextual information, make preliminary observations, record rare events, or note potentially impactful behaviors outside of the regular observation schedule.

## Recording Rules

Recording rules describe how the behavior is recorded. There are two categories of recording procedures: continuous recording and time sampling. Instantaneous sampling and one-zero sampling are two commonly used types of time sampling.

## Continuous Sampling

The purpose of continuous recording is to obtain a complete record of the behavior and provides the only means to understand sequences of behaviors. In continuous recording (often referred to as all-occurrence recording), every occurrence of the behavior and the time of each event is recorded. For states, both the time the activity began and the time it terminated are recorded, while only a single time point is recorded for an event behavior. Continuous recording is designed to provide accurate frequencies, latencies, and durations of all behavioral events and states. One problem that may arise with continuous recording is when a behavioral bout has a long duration. The longer the duration, the more likely the recording session will terminate before the end of the behavior and the record will underestimate the actual duration. In addition, the record can underestimate the duration of an activity if the animal goes out of view. Again, this is most likely to occur if the behavior typically has a long duration. One of the drawbacks of continuous sampling is its practicality. It is more difficult on the coder to record time and duration of every behavioral event or state. This means that only a limited number of behavioral categories can be accurately coded at any time. The likelihood of missing behaviors increases as the number of behaviors increases in the ethogram, resulting in decreasing reliability (Martin and Bateson 2007).

## Sequence Sampling

Sequence sampling is an observation technique used to describe an interaction sequence. It is necessary to use continuous recording procedures when using a sequence-sampling method. The sampling period begins as soon as the interaction of interest begins. The observer then records all behaviors in order of occurrence until the interaction is interrupted or terminated. The next sample period then begins upon the start of a new interaction sequence. In sequence sampling, the observer is focused on interaction behaviors rather than on any individual in the group. This type of sampling procedure can be used to study social behavior. Within a sample period, sequential sampling is similar to focal-animal sampling with

each member of the interaction acting as the focal animal. Each behavior performed by these individuals is recorded. Within an observation session, there will be differences from a focal-animal sampling procedure since the sampling period ends with any interruption or termination of the interaction. The next sequence then may be initiated by different members within the group.

There can be problems with this type of observation procedure. When the observer selects the next available interaction initiation or one that occurs in close proximity to the previous interaction, this new interaction might not represent a true independent sample. However, it is difficult to describe a procedure for selecting interaction sequences at random. It can also prove difficult to specify the beginning and ending of an interaction. One of the advantages of this technique is that it allows large samples of social interactions to be studied. During an interaction, the observer is able to direct attention to the focal animals. The observer then moves to the next available sequence creating little time in which data is not being recorded.

### Instantaneous Sampling

In the instantaneous sampling procedure, behaviors are recorded at specified time intervals. An example of this type of procedure would be observing an animal's behavior at a point in time every 5 min on the minute throughout a 12-h period. Typically, instantaneous sampling is used as a measure for studying states rather than events. This procedure can be used to study the behavior of an individual or a group. For groups in which all members are visible at the specified time point, the behavior of the group can be considered a simultaneous sample. The state of each individual should then be recorded at the same moment. It is not always possible for the whole group to be observable at the same time. In this case a scan sampling procedure should be used.

The instantaneous sampling score is the proportion of the total number of sampling points an animal was engaged in a particular activity. In the case above, in which a sample was taken every 5 min for 12 h, there would be a total of 144 sample points. If an animal was engaged in a certain

behavior on 50 of these sample points, the instantaneous sample score would be  $50/144 = 0.35$ . The instantaneous sampling score is a unitless score. Since individual sample points within a session cannot be treated as independent measurements, only one score is obtained for the entire session. Instantaneous sampling is appropriate for measuring percentage of time an animal engages in an activity. This is also a useful technique for measuring group synchrony. Instantaneous sampling is not an appropriate measure for studying rare behaviors, which have the risk of being missed at any given sample point. It is also possible for there to be bias in instantaneous samples because observers are often more likely to include noticeable or interesting activities that occur just before or after a sample point as occurring within that sample point.

### One-Zero Sampling

In one-zero sampling, behavior is observed during specified time periods, and the occurrence or non-occurrence of a behavior is recorded. Frequency is not observed, only whether or not a specific behavior occurred. A behavior can be considered as having occurred if it was in progress at any time during the sampling point. In one-zero sampling, typically only one individual or pair is recorded during each sampling point. Sampling periods are typically very short, only lasting a few seconds, with a series of sampling periods in succession. In interpreting data from one-zero sampling procedures, the number of sample periods in which a behavior occurred is reported as a percentage or proportion of the total number of sampling periods in a session (Altmann 1974). One-zero sampling is also used similarly to instantaneous sampling in which the presence or absence of a behavior is recorded at a definite time point (as opposed to time interval). These records are still calculated as a proportion of the total number of sampling points in a session. A single one-zero sampling score will be obtained for each sampling session, since, like instantaneous sampling, each sampling point within a session is not an independent measure (Martin and Bateson 2007).

One-zero sampling has been used to measure both states and events; however, there are certain

limitations with this observation technique. When using one-zero sampling to measure states, it is possible for an activity to start in one sampling period, continue into another sampling period, and end in a third sampling period. Using one-zero sampling, this single activity would be scored three separate times. It is also possible to observe an activity being initiated and terminated three different times within a single sampling interval. This would only be scored once as one-zero sampling does not take into account the frequency of the behavior during the sampling interval.

It is important to consider both the typical duration of the behavior as well as the typical interval between occurrences of the behavior. The sample intervals need to be shorter than both the typical behavior duration and the typical interval between behaviors. Many researchers do not believe that one-zero sampling provides an accurate measure of duration or frequency of behavior. This is true whether one-zero sampling is being used to measure states or events (Altmann 1974). Others have suggested that for behaviors that start and stop frequently and which last for very short periods of time (e.g., play behaviors), one-zero sampling is an appropriate measurement to use. The benefit of one-zero sampling is the ease of the scoring procedure.

### **Advantages and Disadvantages of Time Sampling**

One drawback of time sampling (both instantaneous and one-zero sampling) is that neither provide an accurate measure of frequency or duration. In one-zero sampling, because of the assumption that the behavior lasts the entire duration of the sampling interval, there is a tendency to consistently overestimate the duration of a behavior. Another disadvantage of time sampling procedures is that they cannot be used to describe the sequence of behaviors.

One of the benefits of time sampling procedures is the ease of the recording process. By reducing how often a behavior is recorded, the ability to record a greater number of behaviors

and behavioral categories increases. There must be a balance then between maximizing this benefit and obtaining the most accurate representation of frequency and duration. Instantaneous samples with short intervals produce a close approximation of the continuous record and can provide a more accurate measure of duration. As the sample interval is shortened, the benefits of time sampling are diminished. Time sampling procedures also provide the possibility of studying a larger number of animals, something that is difficult to do when using continuous sampling. In addition, time sampling procedures are more likely to have reliability and ensure that every sample point accurately describes what occurred during that time point. For certain behaviors that occur too rapidly to observe every occurrence, time sampling can provide a better means of observing these behaviors than continuous recording.

### **Sociometric Status Matrix**

A sociometric status can be constructed to describe the interaction between two individuals. A table, or matrix, is constructed with the behavior or outcome for the actor listed in rows and the behavior or outcome for recipients listed in columns. The objective of this type of procedure is to determine for each pair in a group the degree of one-sidedness that exists in the relationship. This type of procedure has been used to determine the outcome of aggressive encounters between two individuals. This type of matrix can describe whether one individual in the pair is more likely to be the loser.

### **Recording Medium**

Once the measurement procedure has been identified, the researcher must decide what process will be used to record the behaviors. There are several options available (i.e., video recordings, verbal descriptions, check sheets, automatic recording devices, computer event recorders) (Martin and Bateson 2007).

**Video recordings.** These provide an exact record of the behavior. Video offers flexibility in terms of repeated playback and slowed playback speed that can assist an observer in recording the behaviors present. Audio recordings of vocalizations and acoustic data provide the same benefits and are used in much the same way as videos of behavioral data. Video can also be analyzed in different ways at different times, which allows for multiple questions and studies to be developed from the same video data. It also aids in the processing of timing behaviors for duration and produces a more accurate measure than when coding live in real time. With video data, it is still necessary to code the behavior. Coding is the process of identifying and describing the behaviors that occurred during the recording. This can be done based on an ethogram developed for the study. Typically, an observer will record behaviors observed on the video on a check sheet or computer event recorder. Video recording should be used when there is a specific reason for doing so, as for example, if the behavior requires repeated or detailed analysis. This type of recording can be time stamped and can be helpful to have proof that what was described was actually observed. For studies on behaviors that are rare, it can be useful to have video as a permanent record of what was observed. One drawback to the use of video is that it can be time consuming. It may take hours of observation to code a few minutes of video recording. In addition, one is limited by the field that was actually captured on screen. There may be details that are missing from the video record that could have been captured during live observations.

**Verbal descriptions.** Descriptions can be provided through physical notes or through audio dictation. These recordings are beneficial during preliminary observations or as a means of describing rare events that are not a part of the current study. This type of recording is often coded similarly to video data. This has the same drawbacks as when using video data. This coding process can be time consuming and take up to ten times longer than the original observation.

**Automatic recording devices.** Technology advances have introduced devices and techniques

that can produce a signal when a particular behavior or vocalization is performed or when an animal moves to a specific location in a test chamber. These devices are designed to produce a digital record that can be used for analysis. Some of these devices include activity monitors that automatically record movements. These work through various means including infrared, ultrasonic, capacitive, and microwave detectors. There are physiological detectors that provide automatic measurements of heart rate, temperature, blood pressure, electromyograms, and electroencephalograms. These devices can work remotely which further facilitates the observation process and allows data to be collected more easily and efficiently.

**Check sheets.** In a typical check sheet, columns indicate categories of behavior and rows indicate successive sample intervals. It is important to include information such as date, time, and subject at the top of the sheet. Check sheets provide an inexpensive and flexible technique for easily recording behavior in real time. At the end of a sample period (typically denoted by a signal from a timer), the recorder simply moves to the next row and starts recording all behaviors that occur within that sample interval. This type of recording can be used with different types of observational methods (e.g., focal-animal, scan sampling, ad libitum sampling). It is common to use different parts of a single check sheet for different types of sampling procedures during a single observation period. Continuous recording, instantaneous sampling, and one-zero sampling can all be used in a single check sheet. Check sheets are not ideal when duration of behaviors is of interest since you do not indicate the precise time a behavior is observed, only the sampling period in which it was observed. In order to be analyzed, the data from the hand-written check sheet can be entered into a computer. Check sheets are typically done with paper and pencil, and the data is then entered into a computer. It can be a time-consuming and tedious process to convert this paper data into a digital record that can be used for analyses.

**Event recorders.** Computer event recorders and mobile software applications have been

developed that allow an observer to directly input behavior observations directly into a digital format. Typically, a specific keypress is associated with a certain behavior. The software recognizes the key and the time at which it is pressed. There is also the ability to build in modifier keys to provide further detail of the behavior (e.g., actor and recipient). Other programs allow users to directly input their ethogram into the program and record behaviors and times by selecting the appropriate item. A computer event recorder and software applications provide several advantages over a paper and pencil check sheet. Because the time is coded in the keypress, this data can be used to determine accurate durations of behavior. This is not possible with the paper and pencil check sheet which does not have precise times of behaviors. Limitations in size also prevent observations of larger numbers of behavioral categories on a single sheet. A computer event recorder is not limited in this way and can therefore collect data regarding more behavioral categories. It is also possible to observe more rapidly occurring sequences of behaviors. Computer event recorders have an additional advantage over the check sheet because they eliminate the need to convert the paper data into a digital format that can be analyzed on a computer. These recorders also eliminate the need to store large amounts of paper data that can take up substantial physical space. One of the drawbacks to these recorders is that they often do not offer the flexibility of a paper check sheet in terms of immediate modification of a glitch in the program may cause data loss. It is important for the recording device to fit the research question and the behavioral categories being studied rather than trying to alter the way behaviors are recorded to fit the device.

## Validity and Reliability

**Validity.** Validity refers to the ability of a measure to accurately measure what it claims. A researcher studying aggression needs to be confident that the behaviors being observed are the appropriate behaviors to assess aggression. Three things to consider when deciding if a measure is valid are accuracy, specificity, and scientific validity.

Accuracy refers to the extent to which the measured values correspond to the actual values, thus ensuring there is no bias in the measure. Specificity refers to the ability of a measure to describe only what is being measured and nothing else. Finally, scientific validity is the extent to which the measurement procedure reflects the processes being studied.

**Reliability.** Reliability describes how consistent and repeatable a measure is. There are four factors related to how reliable a measure is. Precision describes how free the measurement is from random errors. Sensitivity refers to the degree to which small changes in the true value are reflected by changes in the measured value. Resolution is defined as the smallest change in the true value that can be detected by the measurement. Consistency is the ability to produce the same results over repeated measurements. In studies on animal behavior, the observer is the measurement tool and therefore must be a reliable measurement instrument. There are two aspects of reliability that are important to consider when observing animal behavior. The first is intra-observer reliability or the degree to which one observer obtains the same results when measuring the same thing on multiple occasions. For example, the observer should code the same sample period on two or more occasions, with similar results for each observation time. This should be repeated multiple times throughout the study depending on its length. Interobserver reliability is the extent to which two or more observers obtain similar results when measuring the same time period simultaneously. When a study utilizes two or more coders, it is necessary that both intra-observer and interobserver reliability are ensured.

**Measuring reliability.** One common way of measuring reliability is through a correlation coefficient. A value of +1.0 represents a perfect correlation, and a value of 0 represents a complete lack of any association. A correlation coefficient can be obtained for each behavior category under investigation. The criterion used to determine what value is deemed "reliable" can vary; however, values between 0.70 and 0.80 are commonly used as criterion values. Correlation coefficients higher than these values would be considered indicative of good reliability. There are other

means of calculating reliability beyond the correlation coefficient. The index of concordance is a measure that can be used when nominal or categorical data is used. This technique compares the total number of agreements and disagreements and provides a percentage of agreement. Cohen's kappa is another procedure used to calculate reliability. This value corrects for agreements that are the result of chance alone.

In the event that two observers are not reliable, there are two options for correction. First, the measures can be redefined to make them more restrictive in order to resolve any ambiguity in the measure. Second, it is possible to combine two or more unreliable measures to determine if together they represent a reliable combined measure. This can eliminate redundancy and reduce the number of categories.

Observer bias (also referred to as experimenter bias) occurs when an observer sees what he or she expects to see. In order to avoid observer bias whenever possible, individuals coding for behaviors should not be aware of the research question and hypotheses of the specific experiment. It is also important to consider how the influence of the observer being present can influence the behavior of the animal. It is possible that repeated exposure to the presence of the researcher can habituate the animal to the observer and minimize the effect of the presence of the researcher. Use of automated equipment, discussed previously, provides another means to limit the effect the exposure to the observer can have on behavior. Whenever possible, measures should be taken to limit the likelihood animals will become aware of the researcher and alter their behavior.

## Occipital Lobe

Aditi Gupta

New York Institute of Osteopathic Medicine, Old Westbury, NY, USA

## Definition

The occipital lobe is one of the four primary lobes of the cerebral cortex, which is largely responsible for visual processing. It is located in the posterior part of the brain.

## Introduction

The occipital lobe is the smallest of the four primary lobes of the cerebral cortex and contains the primary function of vision processing (Purves 2012). It is located in the posterior portion of the brain, behind the parietal and temporal lobes. The occipital lobe lies directly under the occipital bone of the skull. The occipital lobe is a part of the telencephalon, which is a division of the forebrain. The parieto-occipital sulcus lies on the medial surface of the brain and demarcates the occipital lobe from the parietal lobe (Mancall et al. 2011). The occipital lobe rests upon the tentorium cerebelli, a thick membranous layer of dura mater that is used to demarcate the occipital lobes from the cerebellum. It receives its blood supply from several branches of the posterior cerebral artery (PCA).

## Visual Processing in the Occipital Lobe

The occipital lobe can be divided into several anatomical regions, including Brodmann areas 17, 18, and 19, which are arranged hierarchically

within the occipital lobe (Mancall et al. 2011). The most notable region is known as the primary visual cortex (V1) or Brodmann area 17. The primary visual cortex is located on the medial side of the occipital lobe within the calcarine sulcus. If the V1 is stimulated, the person reports flashes of light. To understand the function of the primary visual cortex, it is helpful to understand the basic pathway of visual information (Tsuchitani n.d.). Visual information travels from the retina by the optic nerve, which becomes the optic tract after the optic chiasm, towards the thalamus (Grill-Spector 2015). The visual information arrives at the lateral geniculate nucleus of the thalamus where the axons synapse. The final stop of the basic visual pathway is the **primary visual cortex**, which is located on the medial aspect of the occipital lobe. Visual information may undergo further visual processing in the temporal and/or parietal lobes. There are two pathways for visual information to undergo further processing, which both originate in the occipital lobe: the ventral pathway and the dorsal pathway. The ventral stream projects information to the temporal lobe and results in knowing what the particular object is. The dorsal stream projects information to the parietal lobe and is involved in knowing the location of an object. Another notable area of the occipital lobe is the lateral occipital complex that has been found to hold distributed representations, which can be understood as the usage of spatial activity patterns to create a specific representation of objects (Ishai et al. 1999). The occipital lobe also contains peristriate regions, which are involved in the perception of shape and colors, discrimination of movement, and visuospatial processing.

## Damage to the Occipital Lobe

Damage to the occipital lobe results in visual defects, ranging from partial or complete blindness or visual agnosia, which can be defined as the inability to recognize or interpret visual information. The degree of blindness or visual agnosia depends on the exact location and the severity of the damage. Bilateral damage to the occipital

lobe, most often the result of cerebrovascular disease, can result in cortical blindness or Anton's syndrome, which is a form of anosognosia (Maddula et al. 2009). Anosognosia occurs when individuals have an unawareness of their own disorder or defect. In the case of individuals with Anton's syndrome, the patients behave and act as if they can see, despite their loss of sight, which usually presents with confabulation or the creation of false memories (Sacks 1985).

Injury to one side of the occipital lobe results in homonymous hemianopsia, which is loss of vision of the same field in both eyes. A lesion in the primary visual cortex results in a scotoma. A scotoma can be defined as an area of decreased light sensitivity on the retina (Cheung and Legge 2005). Some visual information is still available to those with scotoma so some people can still react to stimuli even though there is no conscious perception of them, which is known as blindsight (Danckert and Goodale 2000). Occipital lesions can cause visual hallucinations, while lesions in the parietal-temporal-occipital association area are associated with color agnosia, movement agnosia, agraphia, and alexia.

## Occlusion

Shane Peters  
Hofstra University, Hicksville, NY, USA

### General Information

Occlusion derives from the Latin *occludere*, a verb that means “to close up.” Its origin should provide an obvious hint regarding its utilization in the modern day: when something is occluded, it is blocked off or obstructed (McCoy 2013). Vascular occlusion, which occurs when a blood vessel is clogged, is responsible for many morbidities commonly associated with ischemia. Ischemia occurs when blood supply to tissues is restricted, depleting the downstream tissue of molecules like oxygen and glucose needed to keep the tissue alive through cellular metabolism. A common example of an occlusion is that of a coronary artery, called a myocardial infarction, that leads to heart attacks; the occluding agent in heart attacks is often a blood clot that blocks the passage through the artery, obstructing blood flow (Ferdinandy et al. 2014).

Common jargon related to occlusion includes terms like thrombus, embolus, ischemia, and infarction. A thrombus is a blood clot that forms in the blood stream or in the heart, while an

embolus can be anything that travels in the blood vessel until it reaches a vessel too narrow to let the object pass. When the object cannot pass through this smaller vessel, an embolus blocks blood flow and leads to occlusion. An embolus can be a myriad of objects such as fat, a tumor, or even a foreign object. When a piece of a blood clot breaks off and then gets stuck due to a narrow vessel, this agent is referred to as a thromboembolus because it is a blood clot that formed in the artery or vein and was too large to continue through the blood vessels. As expected, an embolus is more common in narrower arteries (Welch 1899). Recall that ischemia is the result of a decrease of blood supply to tissue that results in tissue dysfunction or even death due to the depletion of metabolic nutrients. An infarction results from prolonged ischemia and refers to the death of tissue due to the loss in blood supply (Fluri et al. 2015).

### Occlusion and Stroke

Stroke incidence and related fatality rates have been in a decline due to several implemented measures meant to control cardiovascular risk factors such as cholesterol or smoking cessation programs (Mozaffarian et al. 2016). In addition, the decline can be contributed to improved prevention and care once acute strokes occur (Jauch et al. 2013). While the decline in the number of stroke in the USA has fallen around 18.2% and the fatality rate has declined by 33.7%, this does not mean strokes are not as impactful on the population. This substantial decline has only lead to stroke becoming the fifth leading cause of death in the USA, instead of fourth. In fact, it has been reported that in 2013, 1 in 20 deaths in the USA were due to stroke, with a stroke occurring every 40 seconds and a death due to stroke occurring every 4 minutes in the USA alone (Mozaffarian et al. 2016). Still, this is a major improvement from just 5 years prior, as stroke was ranked as the third leading cause of death in the USA in 2008 (Jauch et al. 2013).

Like myocardial infarctions, large strokes are usually the result of at least one large vessel occlusion that leads to decreased blood flow and

eventually ischemic injury regions of the brain such as the ► [hippocampus](#) or the ► [hypothalamus](#). These ischemic strokes are referred to as cerebral infarctions. Brain imaging is often a priority to understand the location and size of the occlusion. Occlusion of a large vessel, such as the middle cerebral artery or MCA, leads to increased density in a CT scan of the brain. A large vessel occlusion often causes a severe stroke and helps predict neurological deterioration. A hyper-dense MCA can be seen in up to half of thromboses, or blood clotting (Jauch et al. [2013](#)).

### Animal Models of Ischemic Stroke Involving Occlusion

Due to the significant effect of strokes on society, there is a keen interest in the scientific community to study the effects of large vessel occlusion in arteries such as the MCA. Due to the nature of occlusion studies, it is easier to study the mechanisms of occlusion and stroke in animals than it is to experiment with the effects of large vessel occlusions on human participants due to concern for welfare. Studies using animal models have greatly expanding the knowledge around mechanisms of occlusion and have proven to be of great benefit to stroke patients. Rats and mice commonly serve as models of ischemic strokes, but there exist many different animal models. The use of animal models in stroke research has aided our understanding of the physiology and pathology of stroke in humans. Many of these animal models are considered induced models, a term that refers to animals in which the condition is caused experimentally. For the rats used in many occlusion studies, an occlusion is introduced that induces the stroke (Casals et al. [2011](#)).

There are many occlusion mechanisms to induce ischemia, such as blood vessel constriction, infarction, middle cerebral artery (MCA) occlusion, and macrosphere embolization. MCA occlusion is performed by injecting blood clots to obstruct circulation through a carotid artery into the head, which then go on to block blood flow. Artificial macrospheres between 100 and 400  $\mu\text{m}$  model occlusion of the MCA using sutures, while

microspheres around 20 to 50  $\mu\text{m}$  occlude smaller vessels. Macrospheres are injected into the internal carotid artery and lead to focal, or localized, ischemic lesions, while microspheres are inserted into either the MCA or the internal carotid artery and lead to multifocal infarcts. These artificial spheres are injected into vessels to obstruct blood flow and induce ischemia, like the injection of blood clots (Fluri et al. [2015](#)).

Endovascular filament middle cerebral artery occlusion is an animal model specific to rats and later adapted for mice of focal cerebral ischemia that was developed in 1986. It consists of a filament or intraluminal suture that obstructs blood flow when inserted into the vessel at the base, or origin, of the MCA; the occluding agent can be inserted and removed periodically at will to restore or obstruct blood flow, or left in the vessel permanently. When the MCA is reperused, or re-oxygenated, via the withdrawal of the suture, this is referred to as transient middle cerebral artery occlusion. The longer the artery is occluded, the more severe the ischemic change in the tissues that the artery leads to (Ansari [2011](#)).

### Other Forms of Occlusion

Occlusion is not specific to the blockage of blood vessels and is used in dentistry and visual psychology as well. Dental occlusion refers to how the upper and lower teeth touch each other when the jaw is closed, with malocclusion referring to when the teeth do not close properly (McCoy [2013](#)). The occlusion of a retinal artery slows blood flow to the retina, causing vision loss in the ischemic retina due to dysfunctional tissue (Moshiri [2015](#)). External of our body, visual occlusion occurs when a view is obstructed in some shape of form. Studies have shown that as occlusion increases, the ability to process visual movement, or ► [optic flow](#), deteriorates by having participants catch tennis balls while wearing spectacles that provided ► [vision](#) at specific frequencies. As the duration of occlusion increases, it becomes difficult for people to process the ► [perception](#) of ball movement accurately (Elliott et al. [1994](#)).

## Ockham's Razor

Susana Carnero-Sierra  
Universidad de Oviedo, Oviedo, Spain

## Synonyms

[Morgan's Canon](#); [Parsimony](#); [Principle of simplicity](#)

## Definition

This epistemological principle states that, among a few solutions for a problem, the simplest explanation is usually the best.

## Introduction

Ockham was a Franciscan philosopher who lived in the late Middle Ages. Historical sources date his birth in Ockham, England, around 1290 and his death probably in Munich in 1349 (Leahey 2012). He formulated the Ockham's razor principle, a rule of thinking that considers the simplest explanations as more likely to be correct. The name comes from Ockham's reject of Platonism's ideas, cutting through the previous apogee of metaphysics and

opening the age of empiricism. Through the formulation “*Pluralitas non est ponenda sine necessitate*,” Ockham explained the need to discard superfluous interpretations first (Epstein 1984).

This principle is also called principle of parsimony (*Lex parsimoniae*), working as a synonym of this economic view of scientific explanations. Used in a scientific context, Ockham's razor has been employed to test the possible hypothesis that explains a phenomenon, finding an order from simpler to more complex explanations. Popper and the falsifiable method (Popper 1968) established that the assumption of theories is based on the occasions which a theory would fail. Considering the power of the Parsimony principle, the razor principle could be applied and then possible explanations proven false from simplest to more complex. Ockham's razor could serve as an epistemological guide to sort out between different theories that could explain a phenomena (Rodríguez-Fernández 1999).

### Ockham's Razor in Animal Cognition

The Ockham's razor had its own application in terms of animal cognition: it is the Morgan's Canon. Lloyd Morgan was an author who marked the early stages of comparative psychology in the late nineteenth century, investigating animal abilities outside the frame of a human perspective. Morgan applies the Ockham's razor in terms of how to understand psychological faculties in the animal kingdom. The Canon says that if any animal's ability can be explained by a simpler process, it is better than to assume higher faculties are involved. A perfect example of the Canon (in terms of Morgan) or the razor (in terms of Ockham), was the case of Clever Hans (Boakes 1984). Hans was a horse that lived in the early twentieth century, and his owner claimed that Hans possessed the ability of mathematical reasoning, showing that the horse could response correctly to sums through knocking the appropriate number with the hoof in the floor. Pfungst, the researcher responsible for elucidating Hans's abilities, proved that the horse did not reason in arithmetic terms by using the parsimony principle and

thus proving Morgan's Canon. The animal could read the nonverbal expression of its interviewers and detect when to stop knocking.

Parsimony marks the direction in which scientific knowledge explores nonhuman animal cognition, needing complex controls and experimental conditions to prove higher faculties in animals, avoiding humanistic and presentisms bias.

### Implications

The implications of Ockham's razor, apart from how we judge the capacities of other lifeforms, are the ways on how the scientific community accepts or rejects certain revolutionary ideas. This directly connects parsimony with Kuhn's theory of scientific knowledge (Kuhn 1957; Rodríguez-Fernández 1999).

At this respect, taking the simplest explanation as always valid can lead to the rejection of some theories that could be correct, despite being more complex (Gernert 2007). This trend of judgement could bias patterns of explanation in some fields of science, for instance, taking for granted that animals do not exhibit higher cognitive faculties, like numericity perception or language, without exploring all the empirical options and experimental dispositions to show them.

The parsimony was also reformulated in economy of cognitive efforts by Ernst Mach (1897). Mach applied Ockham's razor in his principle of simplicity. This principle says that the cognitive systems clearly prefer the simplest configurations of information, like plain descriptions and simple cognitive paths. Later, cognitive psychology took over from Mach. It is the case of human causal judgement research, in which several research lines have confirmed that humans prefer simplest explanations (Pacer and Lombrozo 2017), because it seems to bring more control of their causal environment.

Parsimony is still a central concept in the evolution of science that remains in effect from its formulation in the fourteenth century to the present day. Following Ockham's formulation of the power of simplest explanations, a few authors have proposed their own version of the razor

principle in different fields like comparative psychology or cognitive research, claiming the time-less relevance of parsimony.

## Oddity

Roger K. Thomas  
Department of Psychology, University of  
Georgia, Athens, GA, USA

## Synonyms

[Matching-to-sample](#); [Mismatch hypothesis](#); [Non-match-to sample](#); [Oddity concept](#), [Oddity problem](#), [Oddity task](#)

## Introduction

The easiest version of the oddity task requires an animal to choose among three discriminanda (typically objects, but sometimes two-dimensional illustrations, or computer images). Two objects are identical (the nonodd objects) and the third, odd object, differs in all properties (color, form, size, etc.) from the nonodd objects. Typically, objects are presented side by side in a row, and the animal learns to choose the odd one. Controls must include varying the position of the odd object (i.e., odd object must not appear predictably in a single position in relation to the nonodd objects). Also, when real objects are used, correct responses are usually reinforced with a bit of food hidden beneath the odd object, control must be use to prevent the animal from detecting the odd object based on the odor of the reinforcer. Inadvertent cueing by the experimenter must be controlled, and other controls may be necessary depending on the design of the oddity task. Assuming all necessary controls are used and the animal attains a statistically significant criterion of correct responses, one may conclude that the animal learned the oddity problem.

## The Oddity Concept

Oddity problems involving the same discriminanda on each trial can be learned by rote via trial and error, which is not of interest to most investigators. Rather, they want to know if an animal can learn the oddity concept. Investigation of oddity concept learning is achieved best by using new objects on each trial, although the same objects may be used more than once, provided the same odd and non-odd objects are never used together twice. Thomas (1996) discussed the kinds of evidence and control procedures necessary to show any kind of concept learning including oddity.

Many investigators using numerous avian and mammalian species have reported use of the oddity concept, but owing to methodological flaws, most conclusive studies with robust results have been limited to research using primates.

## The Oddity Concept: Theoretical Considerations

One of the twentieth century's most brilliant but mostly forgotten behavioral primatologists, Henry Nissen wrote:

Without taking the time now to elucidate the argument, let me categorically suggest that all reasoning reduces to three processes, responsiveness to identity and to difference, and, thirdly, the balance or relevant weight given to each of these. (Nissen 1958, p. 194)

Nissen did not suggest systematic ways to manipulate "the balance or relative weight given to each." However, Bernstein (1961) introduced dimension-abstracted oddity, which moved far beyond the easier oddity concept problems already described. Bernstein used five discriminanda per trial, and to illustrate with one example, five objects differed in sizes and shapes, but four had the same color, a color that differed from the color of the odd object. On other problems, size or shape might determine the odd discriminandum.

### Hierarchies of Oddity Concept-Learning Problems

Building on Bernstein, Thomas and Frost (1983) developed and tested squirrel monkeys on a six-level hierarchy of theoretically, increasingly difficult oddity problems based on variations of color, form, and size, together with manipulation of relevant, constant, and ambiguous cues; constant cues are identical for all objects and ambiguous cues vary among objects in noninformative ways. For example, level 1 (easiest) had three relevant cues; that is, the odd object differed from the nonodd objects in color, form, and size. Level 6 (difficult) might be a problem where all objects differed in form and size, but the odd object and nonodd objects differed in color. The hierarchy can be summarized as follows where R = Relevant cue, C = Constant cue, and A = Ambiguous cue.

#### A Hierarchy of Oddity Problems

1. 3R 0C 0A
2. 2R 1C 0A
3. 1R 2C 0A
4. 2R 0C 1A
5. 1R 1C 1A
6. 1R 0C 2A

Thomas and Frost's monkeys' performances confirmed the hypothesized levels of difficulty except performances were worse on level 3 than level 4. This was explained by squirrel monkeys being protanomalous (deficiency in the retinal cone pigment, erythopsin, which reduces the ability to discriminate wavelengths of light at the red end of the visible portion of the electromagnetic spectrum), and often the single relevant cue at level 3 was color.

Thomas (1996) extended the six levels to ten by adding numerosness as a cue. Thomas (1996) did not specify the ten levels (which the reader can do by following the logic used to develop the six-levels above), but Thomas illustrated an "easy" oddity problem with numerosness as an added cue with two sets of three small white circles as the nonodd discriminanda and two large black squares as the odd one; color, size, and number were relevant. For "difficult," he showed a set of four small white circles, a set of three small black triangles, and a set of two large striped squares. In that case, color, form, and numerosness were ambiguous; size was relevant.

Related to oddity, Thomas also described comparable levels of Sameness-Difference discrimination problems where, typically, two identical or more similar discriminanda must be distinguished from two more clearly different discriminanda. An "easy" example might be two red balls for "sameness" and a green cylinder and a yellow block for "difference." A "difficult" example might be a medium-size small red ball and a large green ball for "sameness" and a small blue block and a large yellow cylinder for "difference." Thus, form is relevant, and size and color are ambiguous.

### Oddity Concept and Learning Set Formation

Harry Harlow, a pioneering investigator of animal learning wrote,

... all concepts ... evolve only through LS [learning set] formation [and] insightful learning through LS formation is a generalized principle [that] appears ... in oddity learning. (Harlow 1959, p. 510)

In Harlow's typical experiment, learning set formation (LSF) was assessed by presenting animals

(usually monkeys) with two new objects for six trials. The experimenter determined which of two objects when chosen would result in a food reinforcer, and the reinforced object's position varied unpredictably to the left or right of the non-reinforced object. The animal had no way to know on trial 1 which of the two was correct. After six trials, two new objects were presented for six trials and the reinforced object's location was varied. The animal could choose only by chance on trial 1, but if it learned to use the information gained on trial 1, it could respond successfully on trials 2–6. Performance on trial 2 is typically used as the best measure of LSF.

Warren (1965) suggested that LSF might be a good way to compare species on learning ability, and he presented a graph where the ordinate was percent correct on trial 2 and the abscissa was the number of six-trial problems. His graph had data for six species. Rhesus monkeys were 85% correct on trial 2 after 400 problems, but rats were 55% correct after 1800 problems. Hodos (1970) presented a similar graph that included 2 human children and 16 additional species. One human child (age unspecified but IQ = 136) achieved 100% correct on trial 2 in 100 problems, a chimpanzee achieved about 95% correct in 150 problems, and a rat achieved 55% in 1000 problems.

However, Warren (1974) changed his opinion and concluded that success on LSF better reflected visual capability than learning ability. Almost all testing had been done with discriminanda based on visual cues, and color was usually an important cue. Old world primates and apes have trichromatic color vision comparable to humans with normal color vision, whereas many mammalian species have poor color vision, and rats have poor vision overall.

### Rats, Oddity, and LSF

Rats have significantly better olfactory than visual abilities, and Langworthy and Jennings (1972) used a simple and inexpensive way to present olfactory discriminanda to study oddity concept learning by rats. Their experiment might also show LSF. They used ping-pong balls saturated with the odors of one of eight food flavorings. Because a given odor might be odd on some

problems and nonodd on other problems, no odor could be associated exclusively with either odd or nonodd.

Three balls, two of the same odors and the third of a different odor, were presented side by side in a mostly open-air chute (please see Fig. 1 in Langworthy and Jennings, 1972, p. 88) in which the balls were inserted. Marks on the chute showed how far the rat had to nudge the ball aside to access the food cup beneath it. The rats' task was to nudge the "odd" ball aside sufficiently to get its food reinforcer. Langworthy and Jennings (1972) reported good results (which Thomas and colleagues later analyzed and found to be statistically significant), but it was unclear whether the food reinforcer was beneath only the odd ball. If so, it is possible that the rats detected the correct ball by smelling the food beneath it.

Bailey and Thomas (1998) also investigated oddity concept learning by rats using odoriferous ping-pong balls. They used 18 odors. With 18 odors used two at a time where either might be odd or nonodd, 306 odor-unique problems can be constructed. Furthermore, because a given odor might be odd on one trial and nonodd on another, no odor was reliably odd. They baited all food wells each of which was covered by a small sliding board. Only the board for the correct choice was moved to expose the food well upon a correct response; so, food odor could not influence the rats' oddity choices. They presented each new problem for 20 trials/day until a rat achieved 16 of 20 correct for two successive days, or until a maximum of 100 trials were presented, after which a new problem was presented. Bailey and Thomas found no evidence of oddity concept learning, because trial 1 performances were at chance levels. However, Bailey and Thomas (1998) found significant evidence of LSF. They found that their four rats averaged 87% correct on trial 2 on problems 16–30 which compares favorably to the chimpanzee's performance seen in the graph in Hodos (1970). Using only first-trial data, one rat had two statistically significant, near-perfect runs, but it did not sustain those performances. Nevertheless, those data suggest that rats might learn the oddity concept with alternative training methods.

## Concluding Remarks

The oddity concept appears to have been investigated in more species than any other concept-learning task, and, historically, it appears that few, if any, nonprimate species have been robustly successful. However, more nonprimate species might be successful with improved methods including that contextual variables (sensory, effector, motivation, environmental, etc.) are suitably adapted to each species (see Thomas 1996), such as, olfactory rather than visual discriminanda for rats.

Greater attention should be given to Nissen's theory (see above) of what most importantly constitutes reasoning, and the hierarchies of oddity tasks and sameness-difference tasks described here provide the means for further investigating Nissen's theory.

## Definition

Oddity concept learning is an ability to identify an odd stimulus from two or more identical stimuli. If the subject can consistently pick the odd stimuli from the identical stimuli across different oddity training tasks and can apply this experience to the novel set of stimuli, it is considered that the subject has acquired oddity concept learning. For example, a stimuli set involves an odd stimulus “Blue circle” and two identical stimuli “Red squares.” Animals are required to discriminate an odd stimulus (blue circle) from the stimuli set

(one blue circle and two red squares). Transfer of the oddity discrimination to a novel oddity stimuli set (e.g., a purple star and two triangles) in the first trial of a transfer test can be interpreted as evidence of abstract oddity concept learning (Wright 1991).

## Introduction

Oddity concept learning has been studied to gain an understanding of comparative learning abilities and the evolutionary origin of animal intelligence (Thomas and Noble 1988). Oddity relates to the same/different (S/D) concept, which is an ability to identify a S/D stimulus from item pairs in discrimination training and its successful transfer [e.g., more than chance level or equivalent to baseline performances (performances of training stimuli during testing trials) that should be 80% or more than 80% correct performances] to novel stimuli in the first trial of the transfer test. Lazareva and Wasserman (2008) opined that responding to members of one stimulus class with a similar strategy and to members of another stimulus class with a different strategy as well as an accurate transfer of training tasks to novel members of the class forms an abstract concept. To study the inter-relations among complex learning, memory, information processing, and perception, an appropriate paradigm should be selected.

The oddity relation is considered abstract because the subject has to be able to store in memory a functional representation of relational understanding between an odd stimulus and identical stimuli (Langworthy 1971). To meet the criteria for evidence of the oddity concept, simply picking an odd stimulus from two or more identical stimuli in a set is not sufficient. Animal subjects are required to identify and retain logical relations among stimuli and to apply this relational understanding to sets of novel stimuli. This relationship does not exist in the physical environment and as concrete entities (Taniuchi et al. 2017). Therefore, to encode the abstract aspects of the discriminative stimuli, higher-order cognition is required.

Rats' abilities to acquire oddity concept learning have been misrepresented because of methodological issues. Past oddity studies (e.g., Koronakos and Arnold 1957; Thomas and Noble 1988; Wodinsky and Bitterman 1953) could not show evidence of oddity learning in rats due to the use of one-odd tasks or two-odd tasks or serial presentation of multiple oddity tasks. Conversely, recent oddity studies (e.g., April et al. 2011; Lazarowski et al. 2019; Taniuchi et al. 2017) were able to show evidence of oddity concept learning in rats by employing multiple concurrent oddity tasks. In this entry, the focus is on the improvement in rats' oddity performances from the original oddity studies (e.g., Koronakos and Arnold 1957; Thomas and Noble 1988; Wodinsky and Bitterman 1953) until today, and some critical parameters (e.g., concurrent presentation, the use of a large number of stimuli) that enabled various species (e.g., rats, monkeys, and pigeons) to demonstrate oddity concept learning. The fact that the same critical parameters also enabled other species (e.g., monkeys and pigeons) to acquire oddity concept learning suggests that these species employ a similar learning strategy to process the discrimination tasks. Testing whether similar neural mechanisms may be in operation across various species during the higher-order learning tasks may advance our understanding about comparative cognition.

Cook, Katz, and Cavoto (1997) concurrently trained pigeons to discriminate odd-item different displays from same displays using a two-alternative forced choice task in which a same and a different display were presented. Each display differed in terms of shapes, pictures, and other elements [e.g., six same pictures (same display) vs. five same pictures and a different picture (an odd-item different display)]. Cook and colleagues found that pigeons could discriminate odd-item different displays from same displays and apply this relational strategy across a variety of simultaneously presented visual items. Although the pigeons showed an acquisition of oddity concept learning with stimuli containing multielements, some perceptual cues became evident in pigeons forming oddity concept learning. The presentation of two or more identical stimuli

along with an odd stimulus in a trial might induce a perception (the process of recognizing and interpreting sensory stimuli) of sameness among identical ones that made an odd stimulus salient by contrast. The sense of sameness among identical stimuli and the salience of an odd stimulus might make the S/D tasks easier for pigeons. Lombardi et al. (1984) also provided evidence in support of pigeons' oddity concept learning. Ten pigeons were concurrently trained with multiple oddity problems dividing them into two groups. One group, the "Few examples group" was trained with five visual patterns. Another group, the "Many examples group," was trained with 20 visual patterns. Different oddity problems were exchanged trial-by-trial. The main training began with a pattern, the sample stimulus, being projected on the middle key. A peck at the middle key created two comparison stimuli, one that matched the sample and another one that had a different pattern. When pigeons responded to the odd pattern, they were reinforced. Whereas, when they responded to the identical pattern, they were punished with 3-s time out and the house light extinguished. After the successful acquisition training, two series of transfer sessions containing novel patterns were conducted. Pigeons of the "many examples" group demonstrated a concept-like rule in demonstrating better transfer than pigeons in the "few examples" groups, suggesting that a larger number of stimuli might facilitate the acquisition of oddity concept learning. Although Lombardi et al. (1984) did not analyze performance on the first trials of test problems, given that they gave no reinforcement feedback on the test trials (extinction test), the pigeons' performances could be attributed to abstract oddity concept learning. This evidence provided reliable evidence that a nonprimate animal could acquire oddity learning based on attending to the relation among stimuli.

In this study, one possible cue may have affected pigeons' discriminative behavior, that is, two presentations of the sample stimulus at every trial may enhance the differentness of nonmatching/odd stimuli that may facilitate pigeons to identify the nonmatching/odd stimuli correctly. Roitberg and Franz (2004) concurrently trained

17 African goats with visual oddity tasks (one odd and three identical nonodd stimuli in a set) simultaneously presented on a screen. The visual stimuli varied and gradually increased at different training phases. After the acquisition of training tasks, goats faced a transfer test involving 24 new discriminanda. Only one of 17 goats showed above chance level performances on the first trial of transfer tests involving new visual patterns. In testing oddity in a sea lion, Hille et al. (2006) suggest that the sea lion used different learning strategies, such as learning specific stimulus properties, the win-stay/lose-shift learning set, and the oddity concept learning, depending on the number of trials given for the oddity problem. When training with a single oddity problem was sustained until correct performance was attained, the sea lion seemed to learn specific stimulus properties because no progressive improvement in performance was observed for 10 consecutive problems. When the number of trials allowed for a problem was limited to 5, the sea lion seemed to use a win-stay/lose-shift strategy, because its performances progressively improved for trials 2–5 of a given problem but remained around chance for trial 1. This suggests that the sea lion's performance on trials 2–5 of a problem was based on the outcome of its response to specific features of discriminative stimuli on previous trials. When only one trial was given for each oddity problem and the win/lose information on previous trials became completely ineffective as a guide for correct responses on later trials, the sea lion appeared to use a relational oddity concept and to respond reliably on the first trials of novel problems. It becomes evident from the reviews of oddity studies with various species that concurrent training and the use of a larger number of stimuli may positively influence performance on oddity tasks.

Compared to monkeys and pigeons, the path of the attainment of oddity concept learning in rats was not so smooth. However, with the continuous efforts of researchers, robust evidence of an oddity concept has been found in rats (e.g., Lazarowski et al. 2019; Taniuchi et al. 2017). Hence, a question arises as to how rats acquired the oddity concept. Were the experimental procedures analogous to those testing other species

for oddity concepts? Monkeys and birds' cognitive abilities might evolve independently or concept learning abilities might evolve in common ancestors of monkeys and birds so that the ability is inherited (Pearce 2008). To compare these two possibilities, examination of concept learning abilities in nonprimate mammals, such as rats, is important. If much similarity in concept learning abilities is found among rats, monkeys, and pigeons, it would support the latter possibility of a common origin of concept learning. Rats can be used as a good animal model for relative class concept learning in pharmacological research. Developments in these areas may contribute to exploring the place of animal research in the study of emergent relations. Oddity discrimination learning has been measured using various experimental procedures. In common simultaneous oddity discrimination training, an odd stimulus and two or more identical stimuli are simultaneously presented in a row (e.g., ABB or BBA). Lashley (1938a) trained rats to choose a cross (X) presented with two circles (XOO) in a three window jumping apparatus or to choose a circle (O) presented with two crosses (OXX) in a stimuli set (concurrent presentation). After the third to fifth reversal, all rats were unable to consistently respond to the odd stimuli. In his subsequent experiments, Lashley (1938b) presented rats upright and inverted triangles on black and striated grounds in which the upright triangles were positive on the black ground and the inverted triangles were positive on the striated grounds.

Lashley's series of simultaneous oddity experiments revealed that rats could not learn the discrimination tasks on the basis that an item (e.g., A) which was correct in a trial might be incorrect in another trial. Rather, they learned the discrimination tasks based on a variety of specific configurations (e.g., XOO, XXO). In detail, rats might follow a strategy, for example, when an odd item X was presented with two identical stimuli OO, responding to item X led to correct solution. Conversely, when an odd item O was presented with two identical stimuli XX, responding to item O led to the correct solution. Simultaneous presentation of oddity problems was employed in other oddity studies with rats (e.g., Koronakos

and Arnold 1957; Wodinsky and Bitterman 1953). Recently, Taniuchi et al. (2017) simultaneously presented an odd stimulus and five identical stimuli (e.g., AAAAAB, BBBBBA) in a row in a wooden made discrimination box. After the presentation of multiple set of stimuli (e.g., ABBBBB, AAAAAB, CCCCCD, DDDDDC), rats were able to show significant test performances on novel tasks. One advantage of this procedure is that subjects have much opportunity to make comparisons between an odd stimulus and identical stimuli (as these ones are presented in a row), facilitating them to recruit some abstract properties from the oddity stimuli set. Non matching-to-sample (NMTS) discrimination task is another procedure to examine oddity discrimination learning in animals. As a measure of conditional discrimination and conceptual learning in humans and nonhuman animals, matching-to-sample (MTS) tasks have been used for over a half century. In MTS procedures, a sample stimulus (e.g., red) is shown to the subjects and then two comparison stimuli (e.g., red and green) appear on the screen. Subjects are typically reinforced for responding to one of the two comparison stimuli that matches the sample one (red). Alternatively, reinforcing responses to the non-matching stimulus is called oddity-from-sample (OFS), mismatching or nonmatching. In the example mentioned above, if subjects are reinforced for choosing one (green) of the two comparison stimuli (red and green) that does not match the sample one (red), it is called NMTS. Simultaneous NMTS implies that a sample stimulus (red) is, at first, presented and then two comparison stimuli simultaneously (red and green) appear. These three stimuli (red, red, and green) remain in view until a choice is made to one (green in case of NMTS) of the two comparison stimuli. Or a sample stimulus (red) is, at first, presented but disappears after some delay and then two comparison stimuli (red and green) are simultaneously presented. Lazarowski et al. (2019) examined identity and oddity learning in rats following the simultaneous MTS and NMTS procedures. In their studies, discrimination training began by inserting the sample tray into the chamber. After removing the sample tray, the

comparison tray was immediately placed simultaneously presenting two comparison stimuli, one of which matched the sample and the other did not match the sample (nonmatching/odd stimulus). In the case of oddity of nonmatching/oddity comparison, a response to one of the two comparison stimuli that did not match the sample was reinforced. In the case of matching comparison, a response to one of the two comparison stimuli that matched the sample was reinforced. Rats were divided into two groups; one was two-exemplar group and the other was 10-exemplar group. Each group was assigned to both MTS and NMTS conditions. For example, the first five training sessions of two-exemplar group belonged to MTS condition and the next five training sessions belonged to NMTS condition. A similar procedure was followed for the 10-exemplar group. After the discrimination training, rats were tested for generalized MTS/NMTS with novel stimuli. Their simultaneous NMTS procedures documented promising proof of oddity concept learning in rats trained with multiple exemplars.

In the case of NMTS procedures, acquisition may be accounted for in either of two ways. For example, if a sample is black and the comparison stimuli are black and red, it is expected that animal subjects may learn to avoid black on the side key, one of the two comparison stimuli (black and red) if sample stimulus (black) is presented in the center key and two comparison stimuli (black and red) appear in the left and right keys. In other words, the subject might follow a responding strategy "After pecking black on the center key, avoid pecking black on the side key." Such a rule (avoiding to peck black on the side key if black is presented as sample on the center key) is called  $S^{\Delta}$ .

But there is another possible candidate, that is, after pecking black on the center key, they may peck red on the side key. This is called  $S^D$  rule (Carter and Werner 1978). Hence, it is visible that in both MTS and NMTS experiments, the sample stimulus appears to function as a cue that facilitates to identify which one of the two comparison stimuli is the correct choice. If the animal subject learns the discrimination tasks on the basis of  $S^{\Delta}$

and  $S^D$  rule with a stimuli set of B (B,  $R^*$ ), his performances would not be better on a transfer trial with a green sample and a green and a blue comparison stimuli [G (G,  $B^*$ )], because he has not experienced these stimuli (green and blue) in previous sessions. According to  $S^{\Delta}$  and  $S^D$  rule, the acquisition of oddity discrimination learning might be limited to the specific features of the stimuli set, contributing to the formation of configural learning (learning the whole gestalt of each stimulus display and learning which comparison choice to make based on this global pattern). For example, oddity performance may drop after yellow has been substituted for blue or green as a sample, because the animal subject has not experienced these configurations involving yellow before. Even if the subject performs well on concurrent problems based on specific configural cues, he would not be able to respond appropriately to test problems consisting of novel stimuli, because when all stimuli are novel, features with already-learned stimuli will be ineffective in dealing with the new stimuli (i.e., transfer). Conversely, if learning is based on stimulus relations at the training phase, it is easy for the subject to apply this relational understanding to any novel stimuli set. Notably, to distinguish the oddity concept learning from configural learning, an examination of the transfer to novel stimuli is needed. According to Nakagawa (1993), concept formation in rats was influenced by some common responses (e.g., pressing the right lever or the left lever or choosing the right goal box or the left goal box), suggesting a responding strategy to associate configurations with lever pressing responses. Take for an instance, when rats went through the NMTS tasks, they might associate one configuration (e.g., ABB and BAA) with pressing the right lever and other configurations (e.g., AAB and BBA) with pressing the left lever. Thus, rats' discriminative choices were mediated by some common responses that might affect subsequent shift problems.

The oddity preference effect (OPE), a tendency to choose one of the two comparison stimuli that does not match the sample, has puzzled comparative researchers for nearly a half century. Wright and Delius (2005), in Experiment 1, trained two

groups of pigeons on matching-to-sample or oddity-from-sample tasks. Half of each group was given a sample reward and the other half received no sample reward. In Experiment 2, two transfer trials were intermixed (quasi-randomly) with six training trials. An oddity group without sample reward was tested with novel stimuli that differed in both color and texture from the training stimuli. Their studies showed that the oddity group without sample reward learned oddity tasks more rapidly than other groups (e.g., matching group with sample reward, matching without sample reward), suggesting that pigeons seemed to pay more attention on oddity comparisons without sample reward than matching with sample reward. In response to the question of how some aspects of experimental procedures contributed to producing OPE, Wright and Delius (2005) explained that, in oddity comparison, providing reinforcement for the selection of one of the two comparison stimuli that did not match the sample presumably increased the possibility to choose the oddity comparison and decreased the tendency to choose the sample comparison. The opposite phenomena might appear if comparison sample was rewarded.

It is worth noticing that discriminative choices are largely influenced by whether sample responding is rewarded. There may have been something common between OPE and the novelty preference in visual-paired comparison tasks. Zola and colleagues (2000) allowed monkeys to view a particular picture for a sufficient time and later gave them an opportunity to view the same picture and a novel picture. An interesting finding emerged; monkeys spent more time viewing the novel picture rather than the familiar picture. To decrease some concerns arising from NMTS, relational nonmatching-to-sample (RNMTS) tasks might be considered in which a pair of sample stimuli (e.g., AA) is, at first, presented and then two pairs of comparison stimuli (e.g., BB & CD) appear. After perceiving the relation between the pair of sample stimuli, the subject is required to respond to one of two pairs of comparison stimuli that does not indicate the same relation as that of the sample. As per the RNMTS, the subject is reinforced for responding to CD rather than

BB. In other trials, CD is presented as sample and EF and AA are presented as comparison pair of stimuli. The subject is reinforced for responding to AA that does not match the sample. In this procedure, no physical feature of the sample stimuli matches one of the two pairs of comparison stimuli. Internal relations between stimuli (e.g., relation between a pair of sample stimuli) rather than a representation of perceived stimulus are an indication of correct responding. So, relational matching rather than physical identity guides accurate choice responding. So far as it is known, RNMTS has hardly been studied with any animal species. Thus, RNMTS might be considered for future oddity studies with rats.

## Types of Oddity Tasks

One noteworthy aspect of previous oddity studies with rats is that animal researchers manipulated oddity tasks in different ways (e.g., one-odd task, two-odd tasks, and multiple oddity tasks). **One-odd task** allows an oddity task (e.g., AAB in which item A is an identical stimulus and item B is an odd stimulus) to be presented until the subjects meet the learning criteria (e.g., 80% correct response). A second task (e.g., CDD) is presented to the subjects in the same way as the first oddity task. In such manner, third, fourth, and so forth discriminations are presented. Koronakos and Arnold (1957) used 5-point discrimination oddity (in which rats had 5 options to make their discriminative choices) with 81-odd tasks to train rats in acquiring oddity concept learning. Rats were trained with each oddity task (one-odd task such as ▲●●●●) until they reached the learning criteria (e.g., 80% correct response). Following acquisition of learning criteria, rats were given second task (◆♣♣♣♣).

The next oddity tasks were presented in a similar manner. Research findings showed that five out of 20 rats could demonstrate gradually improved performances, which Koronakos and Arnold termed as learning set. Single-feature learning (learning based on the specific features of a single item) might be responsible for forming such learning set. It also became evident at the

initial stage of training with one-odd tasks (AAAAAB) in Taniuchi et al. (2017). This task can be solved by learning to respond to a specific item (e.g., item B in the case of AAAAAB), because one-odd task provides an opportunity to a specific item to be an odd item at every trial until the learning criteria is met. With this procedure, the subject may understand that responding to a specific item may lead to reinforcement. In Taniuchi et al.'s study (2017), rats went through the phase 1 training task consisting of one-odd tasks (AAAAAB). Although rats learned the one-odd task, when the same oddity task was reversed and presented as the second oddity task (BBBBBA) where item A was an odd stimulus and item B was an identical stimulus, their performances reached below chance level. It is not clear whether rats learned to approach item B or avoid item A in phase 1 training with the AAAAAB problem. Pigeons' NMTS studies (Zentall et al. 1981) showed that pigeons learned to avoid non-odd stimuli because their performances significantly deteriorated when replacing a matching comparison stimulus but not when replacing non-matching one with a novel stimulus. Similar tests would answer the question of whether rats learn to approach a correct odd stimulus or avoid incorrect identical stimuli in the one-odd task of Taniuchi et al.'s study (2017) with many identical stimuli. **Two-odd tasks** allow correct stimuli to be exchanged between two oddity problems (e.g., AAB and BBA in which item B and A are odd stimuli in the AAB and BBA oddity tasks, respectively) thereby discounting the possibility of learning by responding to a specific item. But there is an advantage of two-odd tasks that the subjects can solve these tasks by memorizing some configuration patterns of stimulus displays (e.g., AAB, ABA, BAA, BBA, BAB, and ABB). It is true that correct responding is limited to some configurations (e.g., AAB, ABA, BAA, BBA, BAB, and ABB) in AAB and BBA oddity tasks and it is possible for the subjects to work out the oddity problems by memorizing these configurations. But according to the criteria of oddity concept learning, the subjects must be able to transfer the training experiences to the first trial of transfer test with novel stimuli. If the subjects learn the

oddity training tasks by memorizing some configurations of stimuli, they cannot solve the novel tasks in the test trials because they will see the new configurations in the test trials that are different from training ones. However, two-odd tasks were reflected in Wodinsky and Bitterman's study (1953) who trained rats to choose a black card (positive) from two white cards (negative). The tasks were reversed [white card (positive) and two black cards (negative)] in the second tasks. Rats could concurrently learn four oddity problems in which positive and negative stimuli were exchanged among some problems. Although these authors found significant learning of four oddity problems, they did not examine transfer of oddity discrimination to novel stimuli, thus their findings could not eliminate the possibility of configural learning (a responding strategy based on the configurations of some specific items). Specific configural "patterns" of multiple stimuli presented together can be an effective cue for discriminative responses. If behavior is influenced by such a factor (control of stimulus configuration), the subject may show chance level performance when novel stimuli are substituted for the training stimuli, because he will see the new configurations in the novel set of stimuli in the testing phase.

**Multiple oddity tasks** involve many items as odd items in the discrimination training tasks. To confirm the acquisition of oddity concept learning, multiple oddity training tasks should be followed by test trials with novel sets of stimuli. Oddity studies with rats manipulated the presentation of multiple oddity tasks in some ways, for example, serial presentation of multiple oddity tasks and concurrent presentation of multiple oddity tasks. Thomas and Noble (1988) trained rats with multiple oddity problems (300 olfactory oddity problems in Experiment 2) serially changing problems every five trials. In particular, they presented rats a single task (e.g., AAB) at a time. Rats were required to discriminate an odd item from 2 identical items. When rats learned this task (e.g., AAB), the task was changed and shifted to the next task (e.g., CCD). In such manner, EEF, GGH, and so on were given to rats. These studies revealed chance-level performance on the first

trials of novel problems although there was progressive improvement of performances on trials 2–5 of a problem that could be attained by just win–stay/lose–shift strategy in which the subject stayed with a stimulus if it was reinforced (win). If rats could encode abstract relational properties of the stimuli set in the acquisition training, it would be evidenced in the first trial of the transfer test involving novel stimuli.

A single task could be solved simply by approaching a specific item. Take, for instance, an oddity task AAB could be solved by responding to item B. The same strategy was effective for the next task, CCD, where responding to item D led to the solution. In a sequential training procedure, learning by trial and error and responding to a specific item can be a simple and effective learning strategy. Abstract relational learning seems unnecessary for solving the task. However, serial presentation of multiple oddity problems resulted in configural learning. Recently, several oddity studies with rats (e.g., Lazarowski et al. 2019; Taniuchi et al. 2017) concurrently presented multiple oddity tasks, demonstrating evidence of oddity concept learning in rats. Taniuchi et al. (2017) trained rats to discriminate an odd object (B) from five identical objects (e.g., AAAAAB) in a row. After acquisition of the first task (e.g., AAAAAB), a second oddity task (e.g., ABBBBB) was added to the training, meaning that, AAAAAB and BBBBBA tasks were concurrently presented to rats (12 AAAAAB and 12 BBBBBA tasks in a session). The two-odd tasks (AAAAAB and BBBBBA) were followed by transfer test 1 involving novel stimuli sets CCCCCD and DDDDDC. Afterwards, novel tasks used in transfer test 1 were incorporated into the training tasks (12 oddity tasks consisting of 4 items A, B, C, and D) that were followed by transfer test 2 consisting of novel stimuli set EEEEEF and FFFFFE. They progressively increased the number of oddity tasks in different phases (e.g., one-odd task, two-odd tasks, and 12 oddity tasks). Their studies demonstrated that one rat (Rat 2) showed significant test performance for novel test sets EEEEEF and FFFFFE after concurrent learning of the 4 training problems with AAAAAB, BBBBBA, CCCCCD, and DDDDDC.

The discussions about the types of oddity tasks reveal that almost of all of the oddity studies with rats prior to 1990 examined oddity concept learning in rats with one-odd task (e.g., Koronakos and Arnold 1957) or concurrent presentation of two-odd tasks (e.g., Wodinsky and Bitterman 1953) or serial presentation of multiple oddity tasks (e.g., Thomas and Noble 1988) that resulted in single feature learning or configural learning. These studies did not use the concurrent presentation of multiple oddity tasks in a training phase and test the discriminative performances with the novel stimuli to confirm the acquisition of oddity concept learning. Recent researchers (e.g., Lazarowski et al. 2019; Taniuchi et al. 2017) made good use of the concurrent presentation of multiple oddity tasks in acquisition phases and tested rats' discriminative performances with the novel stimuli that yielded robust evidence in support of oddity concept learning in rats. Hence, it becomes clear that concurrent presentation of multiple oddity tasks and its transfer to the novel stimuli contributes to rats' oddity concept learning.

### Effects of the Number of Stimuli in Acquiring Oddity Concept

The number of training exemplars appears to be a critical parameter in the development of abstract concept learning. A limited set of training stimuli produces item-specific rather than abstract concept learning in animals, which may be reduced by the employment of a large set of training stimuli (e.g., Lazarowski et al. 2019; Taniuchi et al. 2017; Wright and Katz 2006). To understand which aspects of the procedures led to the acquisition of the abstract concept learning, Katz, Wright, and Bachevalier (2002) considered that the focus on which species had the cognitive capabilities to acquire abstract concepts should have been shifted to the process and mechanisms by which concepts were learned. Thus, Katz, Wright, and their colleagues (e.g., Katz et al. 2002; Wright and Katz 2006) developed the set-size expansion paradigm to employ multiple exemplar training in S/D concept learning. In Katz et al. (2002), monkeys were trained with

8-item sets in experiments 1, 2, and 3 following S/D procedure in which, if 2 pictures were the same, a touch to the bottom picture was reinforced, whereas, if different, a touch to the grey rectangle was reinforced. The set-size was increased from 8 to 16 pictures after six consecutive transfer test sessions. The set-size was further increased to 32, 64, and 128 pictures with transfer test on condition of criterion performances. The findings showed that monkeys' initial transfer was near chance (50%), indicating their dependence on the particular training items and the resulting stimulus displays.

However, transfer performances increased with increasing set-size. In particular, 57%, 71%, 82%, and 87% transfer performances were observed for 8-, 32-, 64-, and 128-item sets, clearly showing that set-size expansion played a critical role in acquiring abstract concept learning. Thus, the size of the training set was instrumental in producing S/D concept learning. Notably, monkeys showed full concept learning with the 128-item set, because their transfer performance (87%) was equivalent to baseline (89%). The role of set-size expansion was further strengthened by Wright and Katz (2006). They conducted experiments with monkeys and pigeons using S/D discrimination tasks in which animal subjects were reinforced to touch or peck the lower picture if two pictures were the same. If different, then a touch or peck to the white rectangle was reinforced. When an 8-item set was presented, subjects showed item-specific learning (learning based on specific physical features of stimuli or configurations of some stimuli). All monkeys and pigeons showed signs of some transfer (partial concept learning that was above the chance and below the baseline) after training with the 32-item set although monkeys showed 14% better transfer than pigeons. The training stimuli were further increased to 64-item sets that yielded improved transfer performances relative to that of 32-item sets. This improvement made the researchers believe that increasing the number of training stimuli might enhance the transfer to a further extent. Thus, they doubled the number of training stimuli and trained monkeys and pigeons with 128-item set followed by transfer test. Monkeys

showed full concept learning with the 128-item set. But pigeons' transfer performances were slightly less than baseline performances. Thus, to confirm acquisition of full concept learning, the stimuli set-size was further increased to 256 followed by transfer testing. Pigeons showed full concept learning. Wright and Katz (2006) proved again that set-size function for monkeys was the same as that of Katz et al. (2002). Set-size function may vary across different species. More specifically, expansion of stimuli set-size (e.g., 128-item set) does not affect various species' cognitive behavior similarly. Some species (e.g., pigeons) need more stimuli, whereas some species (e.g., rhesus monkeys) require fewer stimuli to attain full concept learning. Hence, it becomes clear that an expanded set of stimuli (e.g., 128-item set) may positively influence some species' cognitive behavior (e.g., rhesus monkeys) more rapidly than other species (e.g., pigeons). Thus, it can be said that set-size function might be highly functional for some species (e.g., rhesus monkeys), as a result of which they required comparatively less stimuli to attain full concept learning. Conversely, there are some animal species (e.g., pigeons) that needed a larger number of stimuli (e.g., 256-item set) to attain full concept learning, because set-size function did not seem to be highly functional in them.

From the discussions of Katz et al. (2002) and Wright and Katz (2006), two important factors emerge; full concept learning and partial concept learning. When transfer performances are equivalent to baseline performances (performance with training stimuli during test trials) and both are above 80% correct, it is considered acquisition of full concept learning (Wright and Katz 2006) and indicates that the subjects are making their discriminative responding realizing the relations between transfer stimuli as they are processing the training stimuli. Wright and Katz (2006) found that the larger number of exemplars might be a determinant of whether animal subjects would learn full concept learning or partial concept learning. The greater number of training stimuli may increase the possibility of some features of training stimuli to be shared with any given transfer stimuli. Thus, the number of exemplars during

the training phase has much importance for transfer performances.

It can be assumed that an expanded set of stimuli (e.g., 128 items, 256 items) enriches the categorical knowledge by increasing information on the generic features of the category (as many stimuli contain much information) or by reducing the possibility of some features of a particular stimulus becoming salient. In contrast, when test performances with novel items are intermediate, that is above chance but less than baseline, such a result can be regarded as partial concept learning (e.g., Katz et al. 2002). If animal subjects cannot fully grasp relational understanding among training stimuli or can partly understand which factors are differentiating the S/D item but their training performances still focus on the specific features of a particular item to some extent, partial transfer may be produced when they are tested with novel stimuli. Insufficient variations in the number of training stimuli may contribute to forming partial concept learning. When animal subjects are trained with a small number of training stimuli, they may pay attention to each individual stimulus pair (item-specific learning) rather than understanding the S/D relationship between stimuli of each pair. The animal subjects may learn the same/different aspects of training stimuli at the initial stage of the acquisition phase and associate these aspects with some responses that are reinforced. When novel stimuli are presented, they may utilize this rule more generally once they are able to grasp full understanding of relationships among stimuli. In the case of partial concept learning, they may grasp partial understanding among stimuli in training phase that is reflected in transfer performances with novel tasks. The full concept learning and partial concept learning can better be understood by stimulus control topography hypothesis (Dube and McIlvane 1996), which argues that, when stimuli were presented, stimulus-specific features and stimulus relations both competed to control behavior. Reinforcing a particular feature of stimuli enhanced the possibility of that particular feature to control behavior, because as a result of reinforcing that particular feature of stimuli, an association between reinforcement and that particular feature was formed.

The stimulus control topography hypothesis may be applicable to explain the partial concept learning in which responding to the novel stimuli seemed to be better controlled by generalization from specific properties of training stimuli previously encountered than the sample comparison stimuli. Training with additional sets of stimuli may reduce such control by decreasing reinforcement for responding to two training stimuli and may increase the possibility by the inter-stimulus relation consistently associated with reinforcement. The continuation of multiple exemplar training makes possible relational responding applicable to both novel and familiar stimuli and test performance equivalent to criterion performances: i.e., full concept learning (e.g., Lazarowski et al. 2019). Like monkeys and pigeons, set-size functions have also been found to control responding in rats. Lazarowski et al. (2019) trained 20 rats in a simultaneous MTS and NMTS learning paradigm dividing them into two groups using olfactory stimuli. One group was trained with two stimuli and another group with 10 stimuli as exemplars. Rats trained with 10 exemplars demonstrated high accuracy on the first and second transfer test, whereas rats trained with 2 exemplars did not perform significantly better than chance on initial transfer test. Interestingly, when set-size was expanded for rats originally trained with 2 stimuli and rats were retested with multiple exemplars, acquisition of full concept learning (where training and test performances are equal and both are 80% correct or higher during testing period) was observed. In Taniuchi et al. (2017), when rats faced transfer test 1 consisting of novel problem CCCCCD and DDDDDC after the concurrent presentation of two-odd tasks (AAAAAB and BBBBBA), they did not show transfer. But when they faced the transfer test 2 consisting of novel problems EEEEF and FFFFFE after concurrent presentation of 12 oddity tasks, they showed significant transfer to the novel problems, clearly suggesting that set-size expansion of stimuli plays an important role in the development of relational concept learning. This evidence is consistent with other recent studies (e.g., April et al. 2011) that also showed generalized identity and oddity matching

after training with 10 exemplars. These findings suggest that similar learning processes are functioning across different species in acquiring S/D concept learning.

The basis of stronger transfer with relatively few exemplars observed in rat studies may be that there may be variations in the capacities and the limits in associative memories across different species. For example, monkeys may have more capacity of associative memory as compared to pigeons (Cook et al. 2005). As compared to monkeys and pigeons, rats might have limited capacity to memorize multiple item-specific cues, as a result of which, they might abandon memorizing item-specific cues and start to learn relational cues. Why various species require different numbers of training stimuli to demonstrate evidence of relational concepts is not fully clear, thus requiring further investigation to clarify this issue.

A question arises as to why a larger number of stimuli contribute to concept formation in animals in general. One way to answer this question may be that rats seemed to adopt a memorization strategy to solve one-odd or two-odd tasks. But this memorization strategy would fail, or at least, make learning more difficult when rats faced a large number of discrimination tasks. In the case of 30 oddity tasks, for example, it should be far more difficult to memorize all of the configurations of so many stimuli. Therefore, the large number of tasks might make memorizing the correct responses more difficult (Cook et al. 2005) and contribute to increasing the memory load. This difficulty might have forced rats to give up the memorizing strategy and to switch to a more conceptual-based strategy, the application of an abstract rule that can contribute to reducing the increased memory load (Santiago and Wright 1984). Another reason may be that significant transfer may somewhat reflect generalization from training stimuli to transfer stimuli [if both belong to the same domain (e.g., object stimuli)]. More clearly, when the set-size of the training stimuli becomes sufficiently large, the training stimuli may share some of its common properties (e.g., size, shape, color) with testing stimuli. Animals may sometimes keep such common properties in their memory and transfer to the novel

stimuli on the basis of such similarity (stimulus generalization) rather than utilizing abstract concepts.

If animals constantly respond to the testing stimuli following such rules, their learning would be in a restricted domain [learning that is limited to a particular type of stimuli (e.g., familiar object stimuli–novel object stimuli)]. Therefore, it becomes difficult to rule out the possibility that transfer may be based on some common physical features shared between the novel stimuli and some of the stimuli used in training (Wright and Katz 2006). It should not be assumed that acquisition of S/D concept learning can only be attained by a large stimuli set. Transfer after few exemplars is also common after successive discrimination training with other species and stimulus modalities. Cook, Kelly, and Katz (2003) trained four pigeons in go/no-go successive S/D discrimination procedure in which either same (AAAA... or BBBB...) or different (ABAB... or BABA...) photographic stimuli were presented within a trial. Each array (same or different) was presented for a fixed period of time and was separated by a dark inter-stimulus interval. They were able to learn S/D classifications with up to five different multi-dimensional classes. They also learned and transferred a relational rule when they were trained and tested with photographic (color and gray-scale photographs) and video stimuli in Experiment 3 and Experiment 4, respectively. Cook et al. (2003) reported that successive training with only two exemplars allowed pigeons to transfer same/different responding to novel stimuli. Some possible factors might positively influence pigeons' S/D discriminative choices on novel problems. One of them may be that, in Experiment 3, the gray-scale test had two subtests. The first subtest employed familiar color photographs about which pigeons experienced before. The second subtest employed completely novel gray-scale pictures. The transfer of learning was higher with the familiar gray-scale displays than with novel ones, suggesting that prior experience with familiar gray-scale pictures might facilitate pigeons to show greater responsiveness to these picture stimuli. The other critical factors might be the amount of change occurring in the figures and

background elements of same/different displays. Pigeons faced little difficulty in learning to discriminate same displays from different displays in Experiment 3 and Experiment 4 in which moderate to large changes were brought out between successive items, but, in Experiment 1 and in Experiment 2, pigeons faced difficulty to relationally process the same/different photographs containing very small and centrally located changes. Rensink, Regan, and Clark (1997) found in humans that focused attention was required to direct particular changes or differences between successively presented pictures. Similar phenomena may occur to other species. Pigeons were found to be successful in successive S/D discriminations where large changes occurred from one interval to the next. Very large changes in display may remove the need for providing attention toward any specific place or feature within an image. Considering all of these possibilities, it seemed that pigeons were utilizing image-based memories of the successive stimuli across time. The findings, taken together, revealed that visual relations between elements can control pigeons' behavior. From the comparative discussions on S/D concept learning with various species [e.g., monkeys (Katz et al. 2002), pigeons (Cook et al. 2003; Wright and Katz 2006)], it can be said that S/D concept learning may emerge in animal subjects on the presence of an appropriate experimental procedure.

Although some studies (e.g., Lazarowski et al. 2019) showed generalized oddity learning in rats across a range of odors, it is a time-befitting argument that to confirm the true S/D concept learning, oddity studies across sensory modalities are necessary (Scholtyssek et al. 2013). Thus, it would be of interest to explore the possibility of generalized S/D concept using different stimulus modalities in future studies. Cross-modal transfer tests should be considered, meaning that, training tasks should employ visual stimuli and transfer tests should employ auditory stimuli such that training and test stimuli share no physical features. Several research studies were conducted across different modalities. Giurfa, Zhang, Jennet, Menzel, and Srinivasan (2001) studied bees in order to examine S/D concept learning with

MTS and NMTS procedures. They trained individual groups of bees across different modalities (from olfactory to visual) and found that bees could transfer the MTS or NMTS abilities to novel stimuli that shared no physical features of the stimuli specified in the training. Thus, it could be concluded that the ability of sameness and differences in bees was robust and broad. Such an experimental paradigm should be applied to rat studies in order to confirm their S/D concept abilities across different sensory modalities.

## Conclusion

Evidence demonstrating generalized S/D responding in a wide range of nonhuman species continues to emerge. This progress continues and has been enhanced by some techniques such as concurrent presentation and expanded set of stimuli that determine the efficacy of mediating behaviors, contributing to the development of S/D concept learning in animals. The present entry may guide future comparative cognition researchers on how to attain oddity concept learning in rats that is free from perceptual effect. Notwithstanding, a major challenge is to investigate what mechanisms are in operation in animals' concept formation.

### Definition

The odds ratio is a statistical measurement that helps to understand the comparison of the combined effect of the parameter of each group into a single parameter scale. It is frequently used in medical science and behavior science, especially in control studies cases.

### Introduction

In clinical interventions or interpreting observations of diseases, many statistical tools are helpful in which *odds ratio* plays a frequent role (Montreuil et al. 2005). The ratio of odds ( $odds = \frac{p}{1-p}$ , where  $p$  is the *probability* of the event occurring) is said to be *odds ratio* and is a measure that quantifies the effectiveness of the association between two happenings or events (Szumilas 2010). It is also useful to determine

the odds of the outcomes for two groups (Montreuil et al. 2005). It can be easily evaluated whether the odds are the same or different (Szumilas 2010). *Odds ratio* measures the *odds* (events) in the presence of exposure to the *odds* (events) in the absence of the exposure (Martinez et al. 2017). The odds ratio and risk ratio are quite different in their applications and interpretations but there will be high chance of confusion between the *risk ratio* and *odds ratio*. If we are considering the case of any process of making some products in a company, then we will observe the impact of the newly applied process and existing process. Then, the *risk ratio* is the ratio of the probability of unsatisfactory results of the new process to the likelihood under the existing process. However, the *odds ratio* can be a better approximation in some specific cases. If there is a situation of some rare disease that spreads rarely and its data value is low, then the value of *odds ratio* is very close to the *risk ratio*, that is, both have the same approximate value and, in this case, the *odds ratio* can be a good approximation for the *risk ratio* (Montreuil et al. 2005). But otherwise, *odds ratio* and *risk ratio* are quite different.

Apart from betting (which is almost the odds), the *odds ratio* is explicitly used in many fields from a statistical point of view to compare the relative *odds* of outcomes with exposure such as *epidemiology*, *medicines*, control-decision problems, sports, and betting. The *odds ratio* in the field of statistics is the relative chance of an outcome under two or more different situations (Chen et al. 2010).

### Meaning of Odds

*Probability* is quite common and is defined as the ratio of numbers of *positive* concurrences divided by a number of *total* possible occurrences; however, the *odds* is the number of positive concurrences in relation to the number of nonpositive occurrences. The absolute or relative chance of an event of interest happening is generally expressed by *odds (event)* of that event happening and is given by:

$odds = \frac{p}{1-p}$ , where  $p$  is the probability of the event occurring.

When  $p$  is small, that is,  $p \approx 0$ , then  $1 - p \approx p$  and  $odds = \frac{p}{1-p} \approx p$ . But, when  $p$  is not small, then probability and odds are generally not the same, that is, they have different values for the event happening. *Probability* ranges between zero and one while *odds* are positive numbers ranging between zero and infinity. To understand the differences between probability and odds, consider the following simple example: Let us say that the probability of success of any event happening is 0.8, then the probability of failure of event happening is 0.2. But *odds (success)* and *odds (failure)* are calculated as  $odds (success) = \frac{0.8}{1-0.8} = \frac{0.8}{0.2} = 4$ , while  $odds (failure) = \frac{0.2}{1-0.2} = \frac{0.2}{0.8} = 0.25$ .

### How to Calculate the Odds Ratio?

*Odds* are determined with the help of probabilities, that is,  $p$  is the probability of any events, then *odds* can be calculated as  $\frac{p}{1-p}$  (McHugh 2009). Let us consider the number of exposed occurred events as  $a$  exposed non-occurred events as  $b$  not exposed occurred events as  $c$  and not exposed non-occurred events as  $d$  (Table 1).

The probability of exposed occurred events is given by  $p = \frac{a}{a+b}$

The probability of exposed non-occurred events is given by  $q = \frac{b}{a+b}$

Then, the *odds* of exposed cases are given by  $\frac{p}{q}$

$$\text{i.e., } odds(\text{exposed cases}) = \frac{p}{q} = \frac{a/a+b}{b/a+b} = \frac{a}{b}$$

Now, the probability of exposed occurred events is given by  $m = \frac{c}{c+d}$

The probability of exposed non-occurred events is given by  $n = \frac{d}{c+d}$

Then the odds of exposed cases are given by  $\frac{m}{n}$

$$\text{i.e., } odds(\text{not exposed cases}) = \frac{m}{n} = \frac{c/c+d}{d/c+d} = \frac{c}{d}$$

Now, the *odds ratio* is given  $\frac{p/q}{m/n} = \frac{a/b}{c/d} = \frac{ad}{bc}$ .

Also, since the *odds ratio* is invariant to the reversal of the orientation; therefore, the *odds ratio* for exposure  $\frac{a/b}{c/d}$  is mathematically the same as the *odds ratio* for the occurred events  $\frac{a/c}{b/d}$ , that is, both can be expressed as  $\frac{ad}{bc}$ . Depending upon the above scenarios the *odds ratio* may be interpreted as follows:

**Case 1. When  $OR = 1$ :** the *odds* of the outcome is independent of the exposure. There is no effect of exposure on the *odds* of the event.

**Case 2. When  $OR > 1$ :** The lower *odds* of the outcome is unlikely affected by exposure, that is, exposure is associated with higher *odds* of the outcome.

**Case 3. When  $OR < 1$ :** Higher odds of the outcome is very unlikely to be affected by exposure, that is, exposure is associated with lower *odds* of the outcome.

### Application of Odds Ratio

Behavioral science deals with the interaction and behavior of human beings. It helps us to understand the factors related to psychology or behavior in different case studies. The *odds ratio* is frequently used in the case-control study, which compares two groups of people in which one group has the disease, and the second group does not have a disease. Some examples exhibiting the concepts are listed below:

**Example 1** Suppose that we have data of 370 patients in which 20 of them are having cancer who have mutated genes and 10 who do not have mutated genes. Also, 120 are not having cancer but mutated genes and 220 who do not have a mutated gene.

**Odds Ratio, Table 1** Description of the outcomes and the possibilities

|             | Occurred | Non-occurred |
|-------------|----------|--------------|
| Exposed     | $a$      | $b$          |
| Not Exposed | $c$      | $d$          |

**Odds Ratio, Fig. 1** Data graph of patients

From the above data (Fig. 1), one can determine which fraction is exposed to cancer or not (with the help of probabilities). But the *odds ratio* helps us to find the relation between cancer and the mutated gene.

Case I: The patient has a mutated gene.

The *odds* of a person having cancer are  $20/120 = 0.1666$ .

Case II: The patient has not mutated gene.

The *odds* of a person having cancer are  $10/220 = 0.04545$ .

Therefore  $OR = 3.66 \sim 3.7$ . The *odds* of the person that has cancer are 3.7 times greater than that person will have cancer if they have a mutated gene.

The *odds ratio* is frequently used in a case-control study. In epidemiology *odds ratio* is very helpful to make a comparison with respect to the frequency of an exposure whose impact is evaluated (Cook 2002). Case subject is selected if the outcomes have disease and control subject is selected if the outcomes have not diseased for the case-control study, see *example number 2* (Montreuil et al. 2005).

**Example 2** Consider in lung cancer patients, red wine consumption is 47 among 132 patients (cases). Now, if among 187 patients without lung cancer (controls) in which only 101 patients

**Odds Ratio, Table 2** Description of Association between red wine consumption and lung cancer [7]

| Patients            | Red wine exposure |             |
|---------------------|-------------------|-------------|
|                     | Exposed           | Not exposed |
| Cases (lung cancer) | 47                | 85          |
| Controls            | 101               | 86          |

consume red wine, then Table 2 describes the details of exposed and not-exposed cases:

The *odds* of red wine consumption among cases are  $odds(lung\ cancer) = \frac{47}{132-47} = \frac{47}{85} = 0.55$ .

The *odds* of red wine consumption among controls are  $odds(control) = \frac{101}{187-101} = \frac{101}{86} = 1.17$ .

Thus, the *odds ratio* is (*Odds Ratio*) =  $(\frac{47}{85}) / (\frac{101}{86}) = \frac{4042}{8585} = 0.47$ .

This implies that the *odds* of being a red wine drinker if one has lung cancer are approximately half the *odds* of being a red wine drinker if one does not have lung cancer.

Here, the *odds ratio* is nothing but the ratio of the *odds* of exposure, but clinicians have more interest in the likelihood of diseases. Also, the *odds ratio* has a fascinating property that is invariant to the reversal of the orientation. But the risk factor does not satisfy such property. The *odds ratio* for exposure  $(\frac{47}{85}) / (\frac{101}{86}) = \frac{4042}{8585}$  is mathematically equivalent to the *odds ratio* for the outcome  $(\frac{47}{101}) / (\frac{85}{86}) = \frac{4042}{8585}$ . Therefore, the ratio of odds of

having lung cancer in red wine drinkers compared with nondrinkers is 0.47 (Ruano-Ravina et al. 2004).

- Available evidence to date suggests that it is exhibited by desert ants (Wittlinger et al. 2006, 2007; Wohlgemuth et al. 2001), spiders (Barth 2002; Seyfarth and Barth 1972), honey bees (Tautz et al. 2004), fiddler crabs (Walls and Layne 2009a), dogs (Séguinot et al. 1998), and humans (e.g., Harrison and Turvey 2009; Mittelstaedt and Mittelstaedt 2001; Schwartz 1999; Turvey et al. 2009). A reasonable surmise is that it is exhibited in some form by all organisms.
- Figure 1 summarizes Schwartz's (1999) original investigation of human odometry conducted with blindfolded participants performing a simple homing task. On each trial, the participant went from a fixed starting point A to a variable terminus B – signaled during locomotion by the experimenter – and then attempted to return to A. The participant either walked from A to B with the aid of a long cane or jogged with the aid of a sighted partner. In both cases the participant was distracted so as to minimize the use of explicit strategies such as counting the number of steps. From B to A the participant walked alone without distraction and with the aid of a long cane. As Fig. 1 depicts, whereas jogging from A to B took less time (and involved fewer step cycles) than walking from A to B, the accuracy of the return trip from B to A for each of the distances traversed was the same. Unsighted distance traveled is apparently perceptible by locomotion regardless of duration and style of locomotion (see also Turvey et al. 2009; Abdolvahab et al. 2015).

That natural odometers may differ in significant ways from fabricated odometers is suggested by evidence of the varied means and context dependent nature of biological odometry. Wolf (2011) provides appreciation of the range of methods employed by insects for metering distance. Relatedly, odometric function is independently supported by various perceptual systems, including vision (Ellmore and McNaughton 2004; Kautzky and Thurley 2016; Srinivasan et al. 2000), the otolith organs of mammalian vestibular systems (Israel et al. 1997; Mittelstaedt 1999), and the haptic (i.e., kinesthetic, proprioceptive) system (Seyfarth et al. 1982; Schwartz 1999). For humans, the relative contributions of these perceptual systems can be flexibly adjusted, with the

## Odometry

Odometry refers to the implementation of a specialized procedure or instrument by means of which an organism measures distances traveled.

**Odometry, Fig. 1 (a)**

Homing task performance by blindfolded participants adopting either an outbound walk or jog gait pattern. (b) Patterns differ in the time to complete the outbound. (Adapted from Schwartz 1999)

contribution of vision shown to be greater in more complex environments supporting richer optical structure (Kearns et al. 2002).

Varieties of biological odometry can be interpreted with respect to the contextual constraints (i.e., the conditions of travel) that support the reliable measurement of distance traveled. For optical odometers, the detected rate of optic flow can vary with the properties of the terrain and the organism's height relative to the ground. Of special note, the duration of the so-called "waggle" aspect of the honeybee dance (in the capacity of an odometric measurement) increases at a slower rate when bees fly over water than when they fly over land. For route distances of equal magnitude over land and water, bee perception of distance flown (as indicated by their dances) is smaller for the flights over water. Of additional note, honeybees exhibit a tendency to fly at altitudes that produce a seemingly preferred degree of optic flow (Esch et al. 2001). The latter may relate to the observation on humans that in the driving of automobiles, perceived speed of motion varies as a function of eye height relative to the ground surface (Panerai et al. 2001).

For legged animals, mechanoreceptive organs sensitive to tissue deformation generated by the actions of the limbs during locomotion have been implicated in the measurement of distance traveled (Seyfarth et al. 1982). Haptic odometry of this variety is potentially dependent upon the specifics of legged locomotion, including adopted gait patterns, limb-segment lengths, step frequency, and step amplitude. For example, the haptic odometer of the fiddler crab appears to integrate information generated by limb movements (Walls and Layne 2009a). This stride integrator produces a measure

that depends upon the amplitude of steps (i.e., it is not a step counter) indifferent to slips between end-effector and ground surface suggesting that it is reliable only in measurement contexts supporting sure footing. By contrast, stride integration by the desert ant is sensitive to motion of the limbs relative to the environment, and as such accounts for both slips and stumbles (Steck et al. 2009), as well as undulations in the terrain (Walls and Layne 2009b). The haptic odometer of both desert ants (Wittlinger et al. 2007) and humans (Dominici et al. 2009) depends upon limb length, with lengthening of limbs (by attachments) producing overestimations of distance traveled.

For humans, the haptic odometer has been shown to produce a measure of distance traveled that is reliable across variations in the frequency and amplitude of steps (Schwartz 1999) and across subsets of the variations in gait patterns tested to date (Turvey et al. 2009). Manipulations of gait patterns across the outbound and return phases of simple homing tasks have revealed a human haptic odometer that is reliable across walking and jogging, walking and backwards-walking, and hesitation-walking and gallop-walking (Turvey et al. 2009). The latter two gait patterns are variants of step-to-gait patterns whereby one foot steps forward, followed by the trailing foot stepping next to the leading foot.

Other manipulations of gait patterns in homing tasks reveal a haptic odometer that depends upon the manner in which the limbs are coordinated. With gallop-walk as the outbound gait and walk as the return gait in a homing task, a systematic underestimation bias is observed. Moreover, when the ordering of gait patterns is reversed, so also is the direction of bias (Turvey et al., 2012).

The viewpoint of “gait as odometer” motivates an interpretation of haptic odometry in terms of the space-time structure of gait patterns (Turvey et al. 2009). Motivated by the group symmetry analysis approach of Golubitsky and colleagues (Golubitsky et al. 1999; Pinto and Golubitsky 2006), bipedal gaits can be divided into the so-called primary and secondary gaits on grounds of the group symmetry of the minimal network of identical differential equations required to model them. The spatiotemporal symmetry of primary bipedal gaits (e.g., walk) is dihedral, and that of secondary bipedal gaits (e.g., gallop-walk) is (a lower) cyclic symmetry. Gaits sharing a spatiotemporal symmetry classification are found to measure distance similarly.

The hypothesis of “gait as odometer” implicates a means of measuring distance that depends upon how the limbs are organized in the service of locomotion. Consistent with this hypothesis, in the case of Nordic-walking (handheld poles used to aid propulsion of the body), the manipulation of arm-leg coordination patterns systematically biases blindfolded homing tasks (Harrison et al. 2013). By contrast, matched manipulations of arm-leg coordination patterns in the absence of handheld poles do not produce systematic biases. The results suggest that limbs can be flexibly incorporated in human haptic odometry. The potential significance of such flexibility is evident in analyses of the reorganizations of limbs (in both coordination pattern and functional role) in desert ants dragging food back to the home nest by walking backwards (Pfeffer et al. 2016).

The relevance of the aforementioned faculties for odometry (e.g., Schwartz 1999; Seyfarth et al. 1982; Srinivasan et al. 2000) to the broader challenge of understanding animal navigation can be appreciated in two ways. First, in mathematical and neural models of path integration (Danafar 2012; Glasauer et al. 2007; Hinman et al. 2016; Kim and Dickinson 2017; Kropff et al. 2015; McNaughton et al. 1996, 2006; Ouarti and Berthoz 2008; Stone et al. 2017; Webb and Wystrach 2016) and second in insights into the contextual constraints – such as the ability to recognize places, landmarks, and other features of the environment – that can reset or obfuscate

path integration processes during the navigation of complex environments (Ardin et al. 2016; Warren et al. 2017).

## Definition

The ability to differentiate between intensities of same odor as well as qualitatively distinguish among nonidentical odors.

## Introduction

The sensory process of response to chemical stimuli which gives rise to sensation of odors is known as olfaction. Two types of olfactory receptive areas are present, primary and accessory. The primary olfactory receptive area is the olfactory nerve (Cranial nerve I or C. N. I) innervated region of nose (Figs. 1 and 2) while the accessory olfactory receptive areas are those parts of nose, pharynx and larynx, which forms the respiratory tract and are innervated by chemoreceptive endings of the trigeminal (C. N. V), glossopharyngeal (C. N. IX), and vagus (C. N. X) nerves. The pungent or irritating odor sensation is being perceived by C. N. V but it is not certain that the nociceptive odorous sensation are the only ones being carried by the same, nonetheless it can be said that the part being played by the accessory areas help in olfactory discrimination (Engen 1982).

In humans, the patch of nasal mucosa having olfactory receptor cells are referred to as olfactory mucosa or olfactory epithelium (Figs. 1 and 2) lies in the summit of a constricted passageway termed as olfactory cleft or slit. The slit is 7 cm long as measured from the external nares and this constricted long passage heightens the probability for any inhaled molecule to reach the olfactory mucosal surface, which is being moistened to enable the trapping of the molecules (Moran et al. 1982a).

Olfaction is of utmost requirement for maintenance of life in kingdom Animalia. Phylogenetically, it serves vital purposes in vertebrates, namely, nutrition, communication for reproduction, identification of food (prey), and identification of members of their own species. The taste of the food that we eat is recognized in many instances by the smell of the food; this was documented by a study which asked subjects to identify 21 common food substances placed on the tongue. They noted that there was a decrease from an average of 60% correct to an average of 10% correct when the nasal cavity was made inaccessible to any vapor phase molecules given off by the substances. Even coffee and chocolate, which were correctly identified by over 90% of the subjects when the nose was accessible, were not identified correctly by any subject when the nose was made inaccessible (Moller 2003). This ascertains the fact that the sense of olfaction and its discrimination is essential for evolutionary processes.

## Anatomy of Olfaction

The olfactory pathway can be studied in two parts: olfactory mucosa & neural pathway of olfaction (comprising of olfactory bulb with tract and olfactory cortex).

**Olfactory mucosa or epithelium** (Fig. 3): below the bony roof of cribriform plate of the ethmoid bone the olfactory mucosa has three histological layers, the lamina propria, a pseudo-stratified columnar epithelium, and finally, the mucosal covering.

The epithelium is composed of five principal cell types: olfactory receptor neurons (ORNs),

**Olfactory Discrimination,**

**Fig. 1** Showing primary olfactory receptive area in lateral wall of nose

**Olfactory Discrimination,**

**Fig. 2** Showing nasal septum with olfactory epithelium

sustentacular cells, basal cells, microvillar cells, and finger-like microvilli cells (Polyzonis et al. 1979; Moran et al. 1982b; Morrison and Costanzo 1992; Jafek et al. 2002). The olfactory receptor neurons (ORNs) are sensory for odors and are interspersed with sustentacular cells at diversified stages of maturation in humans.

Sustentacular or supporting cells regulate the homeostasis and proliferation of ORN. Basal cells are the stem cells present above the basement membrane, which divides to form new neural and supporting cells, thus replenishes the steady loss of ORNs (Caggiano et al. 1994; Farbman 1994; Schwob 2005). The microvillar cells are flask-

**Olfactory Discrimination, Fig. 3** Schematic presentation of olfactory epithelium

shaped chemoreceptors with a tuft of microvilli that extends into the mucus layer of the epithelium, a thin axon-like cytoplasmic process extends from the basal pole of these cells and travels through the epithelium toward the lamina propria, rendering a bipolar morphology (Polyzonis et al. 1979). The fifth variety of cell, termed as finger-like microvilli cells were reported by Ota in 1998, who reported their presence only after the disappearance of the olfactory ciliary mat following resection of the olfactory bulbs. Transmission electron microscopy observation revealed that the microvilli of these cells are characterized by a specific core structure consisting of microfilament bundles absent in the microvillar cells, thus differentiating the two. Observing a disconnection between these cells and the postganglionic fibers of the trigeminal nerve and the olfactory bulbs, it was suggested that the fifth type cell could be a mechanoreceptor for a sensory system that is non-olfactory and can play a role in olfactory discrimination.

Among these five types of cells there can be seen two more components, i.e., Bowman glands (Fig. 3) and Olfactory ensheathing cells (OECs).

Bowman glands are branched tubulo-alveolar glands lying under the olfactory epithelium over which its secretion reaches via ducts. The dendritic endings and cilia of ORNs are immersed in the secretion which allows odorant diffusion to sensory receptors as well as the secretion is suggested to play important immunologic functions due to the presence of IgA, IgM, lactoferrin, and lysozyme (Chen et al. 2014).

The OECs were first described in the glial populations of olfactory bulbs in mammals (Golgi 1875; Blanes 1898). Recently, these have drawn much more attention due to their application in regenerative medicine. OECs from olfactory mucosa overexpress genes characteristic of wound healing and regulation of extracellular matrix, whereas OECs from olfactory bulbs express genes suggestive of nervous system development (Guérout et al. 2010; Rela et al. 2010).

**Neural Pathway of Olfaction:** The olfactory pathway is an exception to all sensory systems, as it sends direct impulses to cerebral cortex without relaying them in thalamus. The components of this pathway are bipolar ORNs, olfactory bulb

containing mitral cells, tufted cells and interneurons, olfactory tract, olfactory stria, pyriform area, anterior perforated substance, and septal area in paraterminal gyrus (subcallosal area).

As explained above, the bipolar ORNs have their peripheral processes in the olfactory mucosa while the central processes form the olfactory nerves, which will form synaptic glomeruli with mitral and tufted cells of the olfactory bulb (Halasz and Shepherd 1983).

The olfactory bulb rests upon the cribriform plate and has been highly conserved throughout vertebrate evolution, being absent only in the cetaceans (whales, dolphins) which lack a sense of smell. Its homolog in higher invertebrates (e.g., arthropods) is the antennal lobe. Its functions are to receive and process the information from the olfactory receptor neurons, to send this information to different parts of the olfactory cortex in the forebrain and to provide for integration and modulation of the information by means of pathways from midbrain and forebrain centers. A smaller structure is embedded in the bulb on the dorsal posterior surface and is called as accessory olfactory bulb which transmits information from the vomeronasal organ (Jacobson's organ) via the vomeronasal nerve. The cellular constituents of olfactory bulb include mitral cells, tufted cells (dendrites of both contribute in the formation of synaptic glomeruli with the olfactory nerves) and three interneurons, namely, periglomerular cells (PG), granule cells, and short-axon cells. The olfactory bulb receives a rich innervation of centrifugal fibres from the rest of the brain, which are of three main types: fibres arising from the anterior olfactory nucleus and other olfactory cortical areas, which function as feedback loops for sensory processing; fibres from the nucleus of the horizontal limb of the diagonal band (NHLDB) which are part of the basal cholinergic system innervating the fore brain; and fibres from the midbrain, which are part of the noradrenergic and serotonergic systems innervating the fore brain (McBurney 1984).

The axons of mitral and tufted cells are mainly responsible for the formation of olfactory tract, which extends as backward projection from the olfactory bulb and lodges in the olfactory sulcus.

Each tract has fibres from the opposite olfactory bulb and anterior olfactory nucleus via the anterior commissure. The tract flattens out and divides to continue as medial and lateral olfactory striae and forms an enclosed area in between called as olfactory trigone. The intermediate striae, if present terminates in olfactory tubercle via anterior perforated substance. The fibres of medial striae mostly end in para-terminal gyrus with few passing through anterior commissure to synapse with contralateral olfactory bulb and anterior olfactory nucleus. Whereas, fibres of the lateral olfactory striae makes synaptic contacts with neurons of anterior perforated substance, pre-pyriform region (formed by lateral olfactory gyrus and gyrus ambiens), and peri-amygdaloid region which collectively forms the primary olfactory cortex. The pre-pyriform region continues into entorhinal area (Brodmann's area 28) in the anterior part of para-hippocampal gyrus and projects to the olfactory cortex of uncus, these structures give rise to fibres towards hippocampus forming the perirhinal pathway. The pre-pyriform region, peri-amygdaloid region and entorhinal area are collectively termed as pyriform lobe. Primary olfactory cortex projects fibres to secondary (or association) olfactory cortex (which includes entorhinal area), amygdaloid body, dorsomedial nucleus of thalamus, hypothalamic nuclei and the septal nuclei in order to perceive the odor consciously. These fibers terminate at different levels within the olfactory bulb. The pathways through the medial dorsal portion of the thalamus that reach the orbitofrontal cortex may be responsible for perception and discrimination of odors, while the pathways that reach the amygdala and hypothalamus carry emotional response and physiologic reactions to odors. These pathways may also be responsible for the role of olfaction in eating and for sexually related behavior and reflexes (Shepherd 2006; Gottfried 2006).

Though the olfactory pathway is different from other sensory pathways but in some organisms where vomeronasal organ is active for chemical communication via pheromones between individuals of same species for reproductive behavior, the nonclassical pathway exists where the connections from the accessory olfactory bulb project to

the bed nucleus of the accessory olfactory tract, the medial nucleus, and the posteromedial cortical nucleus of the amygdala. There is no direct pathway from the vomeronasal organ to the cerebral cortex. Discrimination of pheromones and communication with pheromones may therefore occur without conscious awareness. That may be one reason why it has been difficult to establish the role of the vomeronasal system in humans (Bhatnagar 2001).

What Leads to Olfactory Discrimination?

There are a number of factors (Table 1) that has been studied on the part of both the odorant molecule and the animal that are inducing the phenomenon of olfactory discrimination (Table 1). It has been established by Moulton & Beidler in 1967 that the density of bipolar receptors varies from species to species and the boundaries of the olfactory mucosa are not distinct. The dendrites of these receptors extend to the epithelial surface and terminates in a swelling of olfactory knob. These dendrites provide a surface for interactions with molecules. It has long been believed (Parker 1922; Menco and Morrison 2003) that these olfactory cilia contain the olfactory receptor sites where this interaction takes place. The olfactory cilia move in different directions and more slowly than neighboring respiratory cilia, which move

in a more rapid and synchronized manner. This motion may be involved in the displacement of the odorant molecule from the receptor site (Bronstein and Minor 1973).

In 1971, Tucker explained that olfactory receptors are not alone in the nasal passages and are accompanied by the free nerve endings of the common chemical sense that responds to irritating chemical substances. Fibres from these receptors join fibres from other areas of the face and head in the trigeminal or fifth cranial nerve. These receptors are stimulated by many substances, such as automobile exhaust, which may also stimulate the olfactory receptors, and sensations from the trigeminal and olfactory receptors cannot always or easily be distinguished by a human observer but can help in discrimination of the odorants. Psychophysical data from studies clearly shows that what is judged to be odor intensity is partly the result of trigeminal stimulation. The olfactory and trigeminal systems also mutually inhibit each other, such that an odorant may mask an irritant and vice versa (Engen 1982).

In the absence of an accurate measuring entity for olfactory sensitivity as can be done in case of hearing by audiometer, it becomes difficult to establish the amount of an odorant causing a distinct sensory response. The branch dealing with this measurement is known as applied psychophysics. Fechner (1966) originated psychophysical methods for the purpose of describing the

Olfactory Discrimination, Table 1 Factors affecting olfactory discrimination

| Factors in odorants                                      |                                                                   | Factors in animals                                                                             |                                                                   |                                                                                     |     |                                                                  |                                                                                                     |                                                                                                                                                                                                   |                                                                                                                                                         |

| Elicits olfactory sensation easily and in lesser amounts | Large amount of odorant is required to elicit olfactory sensation | Can stimulate C. N. V to elicit noxious sensation and can also help in discrimination of odor. | Elicits response depending upon threshold of the odorant molecule | Depending upon the affinity and threshold of the molecule, the response is elicited |     | Will help to discriminate odors related to pleasurable feelings. | Helps to sense nociceptive odors and is involved in vice-versa inhibition of olfaction with C. N. I | Depending upon the neurotransmitters released in response to the odorant molecule these can either inhibit or excite each other and thus lead to different sensory response to different odorants | If one bulb is stimulated electrically, it tends to suppress the activity in the other bulb, whether the activity is spontaneous or evoked by odorants. |

relation between internal experience and external physical stimulation, between body and mind. The development of psychophysics is one of the key factors in the advancement made in the study of smell. Alas, in absence of an accurate measuring system of odor, the measurement of odor sensitivity and acuity is still made very crudely. Thus, one reads anecdotes about the sensitivity of special people such as Helen Keller, but one never sees any results from objective tests, because there are none (Engen 1982).

## Purpose of Olfactory Discrimination

One is not aware of how much the nonconscious sensory inputs of olfaction is important in daily life. This can be ascertained by an anosmic person who is deprived of more than pleasurable sensations, as the food turns into lukewarm mush, varying only in a few gustatory (taste) qualities and as has been argued that what the nose knows becomes more important in scenario of a hidden fire and increasing environmental pollution (Moncrieff 1949).

The main purposes of discriminating the odors is for

1. Perception of odors may actually dominate visual perception in the selection of food items (Beauchamp & Mailer, 1977). The food may appear to be tasty and fresh but the smell will make all the difference, if the food is actually pleasurable or spoiled.
2. Warning people of contaminated air (with invisible and obnoxious chemicals which can be harmful in small or large quantities)
3. Sexual arousal by pheromones – Although there are disagreements about the definition of a pheromone, there is no doubt that such odorants can initiate sexual activity, serve as warning signals, and delineate trails and territory.

One reason that the sense of smell has been given less consideration than other modalities, especially sight and hearing, is its characterization as the “subtle sense.” As presented in a popular account, odors tend to be concentrated near the ground. So, when our animal ancestors came

out of the water and became upright, they were preoccupied with vision and audition, therefore submitting to the poor olfactory acuity of ours. Olfaction, thus became more involved in visceral and emotional activities than the sensory information transmission (Droscher 1969).

[Elemental and configural perception](#); [Odor detection](#); [Odor processing](#); [Odor representation](#)

## Definition

Olfactory perception comprises the detection and processing of one or several odor molecules ending in the representation (sometimes identification) by the organism of a particular odor, which may be discriminated from another odor. Animals – including humans – detect odor molecules through receptor systems, in which higher organisms are expressed by receptor cells directly connected to the brain. The brain will analyze and interpret the incoming information and display a response if it is biologically relevant. The response may be physiological/neural, psychological (emotion), and/or behavioral. Responsiveness to the information may be either spontaneous (i.e., predisposed) or consecutive to a learning process. In the latter case, after acquisition, the information is stored by the brain and retrieved later on, therefore contributing to the animals' acquired knowledge of the world.

## Introduction

Chemical senses, which comprise olfaction and taste, are likely to be the oldest senses evolved as they are found throughout the animal kingdom. In olfaction, this is true from single cell to higher vertebrates and aquatic to terrestrial organisms. So far no species has been shown to be completely anosmic, underlining the pivotal role of olfaction in survival of all animals.

Odor signals are essential in the adaptation of organisms to their environment and often largely involved in the construction and conservation of social organizations such as flocks, packs, or colonies. Depending on the species: (i) they are used during hunting for prey, to detect its presence, to follow a trail, and to prepare for ambush; (ii) they help to avoid predators or other dangers such as poisoned food or toxic gasses in the surroundings; (iii) they may allow for responses to an alarm substance (alarm pheromone; see below for a definition of pheromone) inducing segregation, as observed, e.g., in fish (Mathuru et al. 2012; Fig. 1A); (iv) or on the contrary they may induce aggregation, e.g., in nematodes (Fig. 1B); mate localization, e.g., in moths (Fig. 1C); or resource exploitation, e.g., in beetles (Symonds and Gitau-Clarke 2016); (v) they are essential to define territories and help in finding back to the burrow or nest, e.g., in birds (Bonadonna 2009); (vi) odor cues emitted by a conspecific may convey information about its gender, kinship, social rank, and health status; (vii) such information, together with information of the owner's reproductive state, may influence mate choice, e.g., in rodents (Ferkin 2018); (viii) odor cues are also vital in mother-young bonding as they allow recognition and attachment of the mother and/or young; furthermore, they contribute in mammals to the orientation of the newborn toward the maternal body and to the location of the nipples (e.g., in mammals Lévy et al. 2004; Fig. 1D).

## Different Organs to Detect Odor Cues

Due to the overall importance of olfaction in the animal kingdom, organ systems have evolved

convergently and show some similarities across taxa, e.g., between vertebrates and invertebrates (Eisthen 2002). The detection systems may be as simple as receptors expressed on the surface of a single-cell organism (Valentine et al. 2008). In insects, the olfactory receptor cells and olfactory sensilla, mainly found on the antennae (Hansson and Stensmyr 2011), detect olfactory cues and transfer the information to the antennal lobe, which processes and relays the learned and non-learned information to the mushroom bodies and/or the lateral horn. In vertebrates, odor molecules reach the nose directly through the nares (orthonasal processing) or indirectly via the mouth (retronasal processing). The vertebrate olfactory system has two major olfactory epithelia, the main and the accessory ones (Brennan and Kendrick 2006). While the first one is typically situated at the back of the nasal cavity and devoted to the detection of volatile cues, the second – vomeronasal organ – involved in the detection of nonvolatile cues is situated at the front of the nasal cavity stretching along the sides of the septum; it may open into the mouth and/or the nose via the nasopalatine ducts. Two other olfactory epithelia have been described in some mammals, the Grüneberg ganglion, which is situated near the entrance to the nasal cavity, and the septal organ, located bilaterally at the ventral base of the nasal septum. The olfactory receptor neurons from the main olfactory epithelium project to the main olfactory bulb, which is the first to relay information to the brain, while the vomeronasal receptor neurons project to the accessory olfactory bulb. From the olfactory bulb, the signal is conveyed to the primary olfactory cortex but also to other brain regions such as hypothalamic nuclei involved in autonomic functions and the amygdala and hippocampus involved in learning and memory. While the vomeronasal organ and accessory olfactory system have long been considered as dedicated to the detection of pheromones, this dogma has been refuted over the last decades through studies showing that they can also process common odor cues and that, conversely, the main olfactory system can process both common odorants and pheromones (Wyatt 2015).

**Olfactory Perception, Fig. 1** Odor perception is important to all animals including humans. Here we are showing some examples of pheromones (composed by single odorants or mixtures) perceived by four different species in different contexts, i.e., fear response, aggregation, mating, and mother-young relationship/nutrition: (A) The perception of predators is essential to survival. In zebrafish (*Danio rerio*) skin damage causes the release of chemicals that elicit fear and escape in members of the shoal. The released alarm pheromone is a mixture that includes the glycosaminoglycan (GAG) chondroitin (Mathuru et al. 2012). (B) The nematode, *Caenorhabditis elegans*, hermaphrodites' aggregation behavior is induced through indole ascarosides (further studies are needed to understand how the chemical language used by this species mediates social communication) (Srinivasan et al. 2012). (C) Sex pheromones may be complex mixtures for which

the ratio of the components plays a key role in its detectability. The female tobacco budworm moth (*Heliothis virescens*) uses a seven-component pheromone blend to attract males of the same species (Vetter and Baker 1983). Among them, two components, (itZ)-11-hexadecenal and (itZ)-9-tetradecenal (in bold letters), are necessary for behavioral activity to occur, while among the remaining five compounds, hexadecanal is most consistent in elevating behavioral activity of males when added to test blends. (D) Olfactory perception is also essential for newborn's survival in mammals. The newborns of the European rabbit (*Oryctolagus cuniculus*), initially blind and deaf, and nursed only once a day for 5 min by the mother, search, locate, and grasp very rapidly the maternal nipples by responding to the mammary pheromone, 2-methylbut-2-enal, emitted by all rabbit females in their milk (Coureaud et al. 2010). (Drawings by N.Y. Schneider)

## Different Behaviors to Convey Odor Molecules to Sensory Organs

In order to make perception of odor molecules or odor mixtures possible, animals have developed diverse behaviors allowing sampling of the

information emanating from the surroundings. These behaviors may help to detect the odor source and the direction to the source or allow for transport of the odor stimuli to specific parts of the olfactory detection organ in species with multiple receptor sides.

Single-cell organisms such as paramecium are unable to detect chemical gradients by simultaneous comparison of the chemical concentration at two parts of the body as observed in multicell organisms. The former possess only one receptor side, while the latter have paired olfactory organs, e.g., two main olfactory epithelia (one per nostril) (Valentine et al. 2008). In order to locate a food source, single-cell organisms use chemotaxis behavior, e.g., they show periods of movement in a straight line interrupted at intervals by a turn. They may “remember” whether the concentration previously experienced was higher or lower than the current concentration.

Multicell organisms can use osmotropotaxis (Gaudry et al. 2012). This strategy depends on measuring instantaneous concentration at two spatially separated odor sensors and turning toward the side of the higher concentration; it was, e.g., described for the fruit fly, which uses its pair of antennae to detect and follow odor cues. A second strategy, which is known as optomotor anemotaxis, involves flying upwind when an odor is sensed (Gaudry et al. 2012). Another orientation strategy is the countertuning, for instance, extensively studied in moths. If the odor of interest is lost, moths switch to cross-wind flight, which may help them track down the odor again. Similar behaviors have been shown also in crustaceans.

Vertebrates appear to combine the use of bilateral chemosensory cue detection with active sampling to localize an odor source. To direct nonvolatile odor molecules to specific receptor sides, specific behaviors have been developed at the receiver level, e.g., the tongue-flicking behavior observed in snakes and other reptiles: The split tip of the tongue allows peaking up nonvolatile molecules and delivering them to the opening of the vomeronasal organ (Daghfous et al. 2012). Similarly, a number of mammals (ruminants, equids, felids, tapirs, and certain marsupials such as kangaroos and wombats) are known to use flehmen behavior which also involves picking up odor molecules with the tongue and applying the attractive nonvolatile substance to the opening of the vomeronasal organ while the head is held up high and the upper lip is retracted. The Asian

elephant uses its trunk to apply female urine to the opening of the vomeronasal organ. Furthermore, mammalian sampling of volatile odor molecules is carried out through a specific action, the sniffing behavior, which induces air entry (or amniotic fluid entry in fetuses) into the nostrils, then the nasal cavity, and, finally, the posterior part of the cavity, where fraction of the flow carrying odorants may reach the olfactory epithelium. Thus, a single sniff, a sniffing episode (successive sniffs), or sniffing cycles (successive episodes with number, frequency, velocity, and duration depending on the species, distance from the odor source, chemical complexity of the source, air turbulence, etc.) distribute the molecules to different populations of olfactory receptors. This allows for actively collecting odor information from the surroundings, analyzing complex olfactory scenes, and responding behaviorally to relevant stimuli (Coureaud and Datiche 2009). Importantly, sniffing also contributes to the temporal, spatial and mechanical coding of a stimulus, to the coding of its identity and intensity, and therefore to the representation of a particular percept for a given stimulus (Mainland and Sobel 2006).

## **Different Modes of Perception to Represent the World**

### **A Complex Olfactory Environment**

In ecological conditions, odors rarely result from single odorants but from mixtures of several – tens, hundreds, or more – odorants, and mixtures are themselves emitted among other mixtures coming from the same substrate or adjacent ones. Whatever the species and their aerial or aquatic living surroundings, animals therefore have to deal with an environment both chemically complex – in terms of number, nature, and diversity of volatile and nonvolatile molecules – and dynamic (e.g., daily, seasonal, anthropic and climatic variations). A common challenge shared by animals during their development, and crucial for survival and adaptation, is then to extract pertinent information from this complexity and to respond efficiently to the cues which are the most

important for them (i.e., those carrying positive or negative hedonic value) by displaying motor actions allowing to meet their needs.

### A Twofold Perceptual Strategy

In terms of perception, since odor mixtures constitute the common stimuli emanating from the physical (e.g., ocean, river, air, ground, rocks, etc.) and biological (e.g., plants, flowers, predators, preys, conspecifics, etc.) components of the environment, animals may simplify the amount of information contained in a mixture either by responding to certain of its elements only (elemental perception) or by responding to the mixture as a whole, i.e., by attributing a particular value to that odor object instead of its elements (configural perception). These two strategies are not necessarily exclusive, because for certain mixtures animals may respond both to a configural odor specific for the mixture and to the odor of one or several of its odorants (weak configural perception).

Elemental perception means that an organism will respond to one or several odorants of a mixture the same way as to the mixture itself or, at least for simple mixtures such as binary ones, that the sum of its responses to each constituent is equivalent to the responsiveness displayed to the mixture (while the level of response to each constituent is superior compared to control odorants) (Kay et al. 2005). This mode of perception makes it possible to reduce the complexity of a mixture by extracting only the information of interest. Elemental perception is, for instance, observed toward key odorants. By key odorants, here we mean particular odorants that convey by themselves, at least in part, the same odor quality as the mixture. For example, in a green apple, humans are particularly sensitive to hexyl acetate and trans-2-hexenal, two molecules that each appear to be strong contributors to the odor quality of that fruit (Bult et al. 2002). This elemental perceptual ability would allow for animals to respond to a complex stimulus through the rapid detection of one, some, or all of its constituents, in order to optimize its knowledge about that stimulus and capability to display preference for it among other stimuli contained in the same

surroundings. In addition, it may allow generalizing its responses from one stimulus to another emitting some common elements (e.g., from one food to another food sharing some odorants and both providing nutritional qualities). In certain cases, key odorants present pheromonal properties and correspond to monomolecular pheromones. By pheromone, we mean an odor cue with communicative value, released by a sender and perceived by a receiver, both from the same species, in which the pheromone triggers an adaptive response (physiological and/or behavioral) independently of previous learning. This is typically the case of 2-methylbut-2-enal, the so-called mammary pheromone emitted by rabbit females in their milk among more than 150 other volatile components: the pheromone strongly triggers in newborn rabbits stereotyped orocephalic movements allowing for the pups to search for the nipples when the mother comes into the nest and to orally seize the nipples during a nursing episode (Coureaud et al. 2010) (Fig. 1d).

Configural perception means, conversely, that the perception of mixture elements is restricted to the benefit of a new odor quality, specific of the whole mixture and clearly distinct from the odor qualities of the elements. It is a way to allow grouping individual stimuli into a perceptual unit – a gestalt – and attributing a specific value to a mixture as a whole (compared to its components), which is represented in the brain as a single unit of information, i.e., as an odor object (Kay et al. 2005). This object then becomes prominent in the environment and easily identifiable by the animal in the midst of other stimuli (Staubli et al. 1987). Configural perception may occur for complex odors emitted from food sources (e.g., flowers or preys in animals, meals in humans) or for odors which carry a social value, as for pheromones constituted by a small number of molecules that blend into a given mixture (Badeke et al. 2016). Configural perception is, for instance, at work in humans, when we perceive the typical odor of coffee, while no molecules of coffee effluvia (bouquet of molecules emanating from the substrate) evoke that odor quality by themselves (Czerny et al. 1999). More largely, it is observed in both aquatic and terrestrial organisms, and in

invertebrates (e.g., spiny lobsters, slugs, honeybees, moths) as in vertebrates (e.g., catfish, rabbits, rats, dogs). Configural odor perception has mainly been described in adults, but data in the rabbit pinpoint its functionality in the newborn (Coureaud et al. 2014; Schneider et al. 2016); the fact that very young organisms perceive certain mixtures as odor objects makes biological sense because of the chemical complexity of the perinatal environment and urgent necessity for individuals, during this early period of life, to extract information from complex odor substrates (amniotic fluid, maternal body, milk) in order to survive and learn about the surroundings. Interestingly, different species may process the same mixtures configurally, as it has been shown with binary and senary mixtures in rabbits and humans (Coureaud et al. 2014; Sinding et al. 2013), which suggests that the sensory systems of various animal species may have converged in the way they process certain complex stimuli, with a common goal: reducing perceptual complexity of their chemosensory environment (chemosensory Umwelt) to detect and behave selectively toward certain odor stimuli that contribute to their adaptation.

Differences in the neural processing supporting elemental versus configural odor perception, from the periphery of the olfactory system to central brain regions, remain to be clearly deciphered. However, certain results suggest that configural perception may occur as soon as odor molecules interact at the olfactory receptor/olfactory sensory neuron level, then in central regions where interactions between neurons occur (i.e., olfactory bulb in mammals and antennal lobe in insects, respectively) and in higher-order regions (i.e., piriform cortex in mammals and mushroom bodies in insects) (e.g., Rospars et al. 2008; Deisig et al. 2010; Gottfried 2010; Wilson and Sullivan 2011; Schneider et al. 2016; Singh et al. 2018).

Among factors that influence the mode of perception of odor mixtures is the number of components. If configural perception can occur even for very simple mixtures as binary mixtures, it is thought that the olfactory system presents elemental limits: when the number of odorants in a mixture becomes too high compared to that limit,

perception would switch from the elemental to the configural mode. In humans, this limit seems to be low (around 4–5 odorants); it appears to be higher in other species (e.g., Sinding et al. 2013). Other factors involved in the way odor mixtures are perceived may also depend on the stimulus, e.g., the chemical nature of the individual components and their ratio in the mixture, or on the receiver, e.g., the animal's experience of the mixture or its constituents. Thus, if certain mixtures are spontaneously processed in the elemental or configural ways, learning events may modulate this initial perception. The respective influences of all these factors in the final perception of odor mixtures remain to be clearly determined.

## Conclusion

From invertebrates to vertebrates and throughout ontogenesis, perception of odor cues is of vital importance to help animals to adapt to the environment in which they are living by displaying responsiveness to certain odorants or mixtures of odorants carrying spontaneous or learned biological values and to build representations about the social and nonsocial components of the environment. Further investigations, from chemistry to behavioral neurosciences, are required to better understand these remarkable sensory and cognitive abilities shared by all species, including humans, aiming to improve their integration into the world through the olfactory modality, alone or in interaction with the other sensory modalities.

## Definition

An omnivore is an organism with a dietary intake consisting of both plant- and animal-derived materials.

## Introduction

An omnivore is defined as an animal that consumes both plant- and animal-derived foods, the prefix being derived from the Latin words *omnis*, meaning “all,” and *vor*, meaning “to devour.” Omnivores can obtain their dietary energy and nutrient requirements from a mixed diet of plant and animal origin and will occasionally include other sources of nourishment in their diet such as fungi, algae, and bacteria. Omnivory can be characterized as behavioral and/or physiological, based on the spatial and temporal availability of foodstuff, combined with an organism's intrinsic ability to obtain energy and other nutrients from ingested material. Certain omnivorous species will demonstrate specific anatomical, physiological, and/or behavioral specializations and adaptations for the acquisition and processing of specific foodstuff.

Omnivores exploit a wide nutritional niche as a result of the diversity of foods consumed. Seasonality and availability of specific dietary components can vary, and some omnivores will demonstrate the opportunistic consumption of available material, either because of nutritional deficit or due to seasonal, temporal, and/or spatial availability. This impacts on both the qualitative and quantitative nutritional requirements of

omnivorous species. The digestive system and oral, dental, and other morphology of omnivores are also highly variable. As a result, generalized observations about the anatomy, physiology, and nutritional requirements of omnivorous species are problematic and tend to be best examined on an individual species level.

## Omnivorous Species

Omnivores are diverse and belong to several different taxonomic clades. Several mammals are acknowledged to demonstrate an omnivorous dietary strategy, with bears and many canid species (Landry and Van Kruiningen 1979) exhibiting a mixed dietary intake of plant- and animal-derived material, including that scavenged. The pig (*Sus scrofa domestica*) is a monogastric (simple, single-stomached) animal often described as a typical omnivorous mammal, with a dentition and digestive system considered intermediate to a typical carnivore or herbivore, whether ruminant or hindgut fermenter.

Several bird species are also considered to be omnivores, with consumed foods including fruits, berries, seeds, nectar, insects, worms, fish, and other animals including mammals, reptiles, amphibians, and other birds. Omnivory is also observed in marsupials such as the brushtail possum (*Trichosurus vulpecula*; Cruz et al. 2012), various reptiles, amphibians, fish, and invertebrate species. The diversity of species in which omnivory is observed supports the biological and evolutionary value of a mixed dietary strategy, where available dietary resources can be exploited in an otherwise inconsistent environment.

## Characteristics of Omnivores

The omnivore dietary strategy is diverse and observed across different taxonomic clades, often each independently evolving digestive capabilities for a mixed dietary intake. Consequently, in contrast to the easily identified physical characteristics of a typical mammalian carnivore such as dentition, identifying specific physical and

physiological characteristics of omnivores is less obvious. Behavioral characteristics will also relate to feeding behavior and how different foodstuffs are acquired and consumed by omnivorous species, and this may relate to both temporal and spatial availability of dietary components.

On this basis, classification of an organism as an omnivore is problematic as generalizations of fundamental biology are limited. For example, the domestic dog (*Canis lupus familiaris*) is recognized to exploit an omnivorous dietary niche and yet has the dentition and digestive anatomy of a typical carnivore. However, there are some characteristics that are common to many species with an omnivorous strategy.

The typical diet of omnivorous species will consist of a mix of plant- and animal-derived material, occasionally also including fungal matter. Consequently, the digestibility of ingested material will vary, and a greater proportion of indigestible, fibrous material will be consumed in contrast with carnivorous species. Physiological adaptations include the metabolic ability to manufacture specific nutrients from appropriate precursors supplied as nutrients, as well as the digestive capacity to deal with food of both plant and animal origin. As a result, omnivores typically have longer and more complex digestive systems, the provision of microbial fermentation in the caecum, and longer mean retention times (MRT) of digesta than observed in highly carnivorous species (Hume 2002). Indeed, the typical omnivore digestive system comprises aspects of both the typical carnivore and herbivore digestive systems, but without some of the extreme digestive specializations observed in the herbivorous ruminants and hindgut fermenters.

Omnivory is further complicated by the observation that species classified as either herbivores or carnivores on a physiological basis exhibit ingestive behavior that contradicts those classifications. For example, cats and dogs are known to occasionally eat grass. This has long been considered a behavioral response to elicit an emetic reaction, although evidence suggests this is not always the case (Hart 2008) and at least in dogs might be a gustatory preference (Ferrell 1984; Li et al. 2006).

Similarly, species typically considered to be herbivorous have been observed to consume animal material, sometimes in an opportunistic, scavenging capacity. This may arise from a physiological need for specific nutrients and/or a behavioral adaptation for nutrient acquisition from available resources during periods of limited dietary availability. Both domestic rabbits (*Oryctolagus cuniculus*) and snowshoe hare (*Lepus americanus*) have been observed to consume the carcasses of other animals, including those of their own species (Clauss et al. 2015; Peers et al. 2018).

Osteophagia (the consumption or chewing of bone) is also observed in otherwise herbivorous species. White-tailed deer have been seen to consume bone from carcasses in an opportunistic manner (Meckel et al. 2017), and osteophagia has been frequently reported in giraffe (Hampton 2002), potentially as an available source of phosphorus and calcium which might be otherwise deficient from their diet (Bredin et al. 2008).

While it is considered that the gnawing or chewing of bone (or other bony items such as antlers) by species predominantly considered to be herbivorous represents an opportunity to supplement dietary mineral inadequacy, boredom, habit, and taste may also contribute to this observation. However, the behavior can result in abnormal tooth wear and breakage, with both health and biological identification significance (Càceres et al. 2013). Rodent species have also been described as chewing on bone to address mineral inadequacies, and it appears to be a significant behavior in reproductively active female crested porcupine (*Hystrix cristata*), potentially to support the mineral demands of pregnancy and lactation (Mori et al. 2018).

## The Omnivore Diet

The proportion of animal and plant material in the diet of individual species will vary, and no set definition is ascribed to an omnivore based on dietary composition, beyond that of a mixed intake of plant, animal, fungal, algal, and bacterial material. Some species routinely consume a mixed diet, while others modify their dietary

intake of plant or animal material based on supply, culture, preference, behavioral adaptations, and seasonal availability. This has been observed in the dugong (*Dugong dugon*), where the seasonality of their usual seagrass diet leads to omnivory (Preen 1995). Other species display opportunistic scavenging behavior, resulting in a mixed dietary composition, such as members of the Canidae (Landry and Van Kruiningen 1979).

There may also be apparent behavior “preference” for specific foods, based on specific digestive system adaptations, and some species can be further classified into specific dietary niches based on the proportion of individual foodstuffs in their diet. This leads to classifications within the omnivore classification, such as the frugivorous (fruit-eating) maned wolf (*Chrysocyon brachyurus*; Motta-Junior et al. 1996), insectivorous (insect-eating), or granivorous (grain-eating). Such terms are useful in identifying what a large proportion of an otherwise omnivorous diet will consist of, and such dietary classifications can be observed across the range of species in which omnivory is observed.

## The Dentition and Digestive System of the Omnivore

Organisms demonstrating a mixed dietary strategy and intake encompass a number of different taxonomic clades and a wide number of species. Consequently, specific characteristics of the omnivore digestive system tend to be more species-specific than dietary intake-specific. However, omnivorous mammals will typically be monogastric with a simple digestive system and minimal reliance on bacterial fermentation of ingested foodstuff, compared to those species identified as herbivorous.

The omnivore gastrointestinal tract is typically more complex than that of carnivorous species, although the stomach remains simple. The omnivore small intestine is typically of moderate length, and the caecum and colon will permit a level of retention of digesta and may exhibit a degree of microbial fermentation (Hume 2002), greater than that of a typical carnivore.

Because of the mixed intake of dietary components by omnivorous species, they tend to have a diverse ability to digest specific nutrient groups (carbohydrate, protein, fat, and fiber). This leads to a diversity in the way that specific nutrients will also be metabolized and absorbed, in addition to specific nutritional requirements.

Bird species with an omnivorous dietary strategy will demonstrate a typical avian digestive system, with crop, proventriculus, gizzard, and duplicated caeca (McDonald et al. 2011), but may have intermediate beak morphology between that observed in birds with dietary specialties such as the raptors (typically carnivorous) and finches (with a typical intake of plant material).

The dentition of omnivorous mammals is typically intermediate to that of carnivorous species and the herbivorous species. Where there is a degree of dietary specialization, dentition may reflect this, although the dentition of most mammalian omnivores demonstrates a greater degree of grinding and crushing surfaces via the molars and pre-molars than would be observed in the typical carnivore dentition. This provides enhanced grinding and chewing ability and is typically combined with altered cranio-mandibular structures and musculature to facilitate prolonged food acquisition and processing.

## Omnivory and Evolution

While the ability to obtain nourishment from a mixed dietary intake, opportunistic and seasonal availability of dietary components may appear an adaptive survival strategy to support life in a changing environment, omnivory may represent a macroevolutionary sink, in birds at least (Burin et al. 2016). This supports the notion that the biological fitness of specialists tends to be higher than that of generalists (Wilson and Yoshimura 1994), although the very fact that omnivory appears to be such a widespread dietary form across a range of organisms does suggest a survival advantage, potentially as a result of inconsistent or unpredictable resource availability.

The evolution of individual species is characterized by the gradual acquisition of adaptations

that enhance reproductive survival. Dietary strategies are clearly integral to the evolution of a species due to the requirement for nourishment for survival, but also because of competition between individual species for dietary resources (Grant and Grant 2006). With omnivory typically representing a generalization and adoption of intermediate physical and physiological characteristics for this dietary niche, the lack of specialization may simply represent reduced biological diversification and, as a result, increased competition for dietary resources within an evolutionary timeframe.

In mammals, different diversification rates characterize the different trophic classifications, herbivore, carnivore, and omnivore, with transitions toward omnivory being more frequent than to either herbivory or carnivory (Price et al. 2012). This might be an indication of the biological value of a generalist dietary intake, although there are significant levels of diversification in the ruminant herbivorous species with different feeding styles (Cantalapiedra et al. 2014), further demonstrating the impact of diet on evolution.

However, birds are well understood to demonstrate specific physical adaptations to specific dietary niches, resulting in highly specialized feeders with physical adaptations in physical (e.g., beak morphology), behavioral, and other physiological characteristics. Species belonging to the Corvidae family tend to have more omnivorous, opportunistic diets (Kissling et al. 2012) and typically demonstrate intermediate physical characteristics in terms of size, beak morphology, and other adaptations, as well as a wider spatial distribution.

Omnivory may also have an impact on the evolution of body size, as is observed within carnivorous species (De Cuyper et al. 2019). Animals of larger body size tend toward herbivory and a greater intake of plant-based material, which is also associated with longer mean retention time for digesta (Hume 2002). In the common brushtail possum, subspecies with a smaller bodyweight appeared to consume more a mixed, omnivorous dietary intake than those of larger body size, supporting the shift toward omnivory or indeed even carnivory in smaller animals (Cruz et al. 2012).

## Conclusion

The omnivore dietary strategy is a generalist one, consisting of an intake of both plant- and animal-derived materials. Dietary intake can vary based on the availability of material either spatially or temporally, but also based on individual species physiological or behavioral preferences. While specific characteristics of omnivorous species are difficult to identify due to the variety of species in which the strategy is observed, at least in mammals and birds, omnivores typically demonstrate morphological, physiological, anatomical, and behavioral traits linked to ingestion, between those of typical carnivorous and herbivorous species.

Omnivory is observed and identified across a wide range of taxonomic orders and appears to be a significant factor in the diversification and evolution of some species. Omnivory represents a dietary niche that permits a range of available resources to be utilized for energy and nutrient acquisition. This can be of significant benefit in unpredictable or limited resource environments and, as such, can be considered a successful dietary strategy.

<sup>2</sup>Department of Biochemistry, All India Institute of Medical Sciences (AIIMS), New Delhi, India

Ontogeny refers to the development and maturation of an organism or an organ from a fertilized egg. The term ontogeny first appeared in scientific literature in 1872 and is derived from 2 words – *onto* referring to individual/being and *genesis* meaning production.

Ontogenesis is determined by various genetic and environmental factors. The stages that occur during ontogenesis are sequential and are extremely specific for a particular species (Cabej

2012). A deviation from the routine ontogenic process at a particular point in development is a major step in speciation (evolution into a new distinct species). Ontogenesis is usually associated with either of the two processes – metamorphosis and allometry.

Metamorphosis (*meta*: change; *morph*: form) is the drastic transformation that occurs to the form of an animal after it has completed the development as an egg. This has been observed in various classes like insects, amphibians and fish. Programmed cell death, also known as apoptosis, plays an important role in metamorphosis, where redundant cells undergo cell death in absence of inflammation, resulting in involution of body parts. Metamorphosis is also regulated by factors like hormones and growth factors (Fig. 1).

Allometry (*allo*: other; *metry*: measurement) is the relationship between the change in size of a body part in relation to the change in size of the organism. If the growth of the body parts of an organism occurs in equal proportions to one another throughout its development, the growth

is considered as isometric (*iso*: same). This is observed in various organisms after metamorphosis, for example, in frogs. Any deviation from isometric growth pattern is referred to as allometric scaling. Allometric changes during ontogenesis are observed in a multitude of species including humans. An example of allometric growth is the size of head in humans during development – the proportion of head size with respect to the body size progressively decreasing, as the growth proceeds. Allometric growth pattern can be mathematically represented by the equation:  $f(x) = ay^b$ , where  $x$  and  $y$  are organ sizes/attributes, and  $a$  and  $b$  are scaling constants. The exponential scaling component of the above equation will be positive and high for an organ/attribute that is important in providing a survival trait for the organism. This is exemplified by the disproportionate growth of antennae and claws in lower animals. In humans, fetal weight is a function of femur length, head circumference, and biparietal diameter (length between two parietal eminences, which forms the part of the skull

**Ontogeny, Fig. 1** Metamorphosis in monarch butterfly (*Danaus plexippus*). Monarch completes its life cycle from egg to larva (caterpillar) to pupa (chrysalis) to adult in a

period of 28–38 days. (Courtesy: USFWS photos by Courtney Celley, Tina Shaw and Joanna Gilkeson)

bones), as determined by ultrasonography. Allometry can also be extrapolated across organisms, for example, metabolic rate in many organisms is a function of body mass raised to the power 0.75 (Kleiber's law).

**Ontogeny, Fig. 2** Recapitulation theory. (Courtesy: Ian Alexander [CC BY-SA 4.0 (<https://creativecommons.org/licenses/by-sa/4.0/>)], from Wikimedia Commons)

Sometimes during the ontogenesis of an organism, features/traits that are otherwise observed only in the juvenile/larval growth stages are retained. This phenomenon is known as neoteny (*neo*: new; *teny*: prolong). A classic example of neoteny is observed in Mexican salamander, also known as axolotl (*Ambystoma mexicanum*), where the larval forms can reproduce and survive. Humans also exhibit neoteny during ontogenesis – development of human offsprings is much more prolonged than nonhuman primates, and this is thought to be the reason behind features like a larger brain and sophisticated emotional responses in humans compared to other primates.

Recapitulation theory proposed by Ernst Haeckel in early nineteenth century states that “ontogeny recapitulates phylogeny.” Phylogeny (*phylon*: tribe) is the evolutionary history of a species as a whole. According to the recapitulation theory, as an organism undergoes ontogenesis, it encounters various stages of

**Ontogeny, Fig. 3** Pharyngeal arches and pouches seen during human development. (Courtesy: Loki austanfell [CC BY-SA 3.0 (<https://creativecommons.org/licenses/by-sa/3.0/>)], from Wikimedia Commons)

development which closely resembles the organism's ancestral species along the evolutionary timeline. In the book *The Drama of the Oceans*, Elisabeth Mann Borgese mentions "Every woman's womb is a micro-ocean, the salinity of its fluids resembling that of the primeval waters; and every microcosm restages the drama of the origin of life in the gestation of every embryo, from one-celled protozoa through all the phases of gill-breathing and amphibian, to mammalian evolution" (Borgese 1975) (Fig. 2).

This concept of recapitulation is now being criticized and may not be as dramatic as Ms. Borgese explains or as Haeckel proposed. Since many organisms do not undergo embryonic stages that mimic all the ancestral forms, the concept of recapitulation is now defunct. Nevertheless, certain ancestral features are observed during ontogenesis, for instance, presence of pharyngeal arches and pouches during human development, and gill slits during the development of frogs, both reminiscent of evolution from aquatic organisms (Fig. 3) (Said 2018).

Reverse ontogenesis is the process by which an organism resorts to a larval stage from an adult stage. This was first described in 1913 in hydrozoans by H.C. Müller, where it acts as a protective mechanism against adverse environmental conditions.

## Alternative Words or Phrases Not Included in the Title

Anxiety, Animal fear, Sensorimotor test, Rodents, Locomotor activity, Exploratory behavior, Thigmotaxis

## Synonyms

[Test for analyzing anxiety-related behaviors](#)

## Definition

Open-field test is used to analyze the different aspects of anxiety-related behaviors, including locomotion and exploration in animals.

## Introduction

The open-field test (OFT) is a well-established and modest sensorimotor assessment employed to evaluate anxiety, basic locomotor-activity levels, and exploratory behavior in animals (Hall and Ballachey 1932). Traditionally it has been used for rodents like mice and rats, but the conceptual design is also used for other species including birds and humans (Uitdehaag et al. 2008; Walz et al. 2016).

The apparatus consists of a square arena where the animal is placed and allowed to freely explore

for a limited (predetermined) period of time. The locomotor and exploratory behavior is recorded using a camera. The video is then analyzed using appropriate software for multiple parameters like total distance covered and total time spent in demarcated areas (not visible to the subject animal). A comparatively decreased locomotion (less exploration) and overall preference to remain close to periphery near wall boundaries (thigmotaxis) imply increased anxiety in the animals (Crusio 2013).

### Usage of OFT

It is very useful in testing the effect(s) of various anxiolytic drugs or new chemical entities on central nervous system. It is also used for phenotyping different transgenic animals for the levels of anxiety. There have been multiple studies done to evaluate the effect of hormonal or nutritional deficiencies (Bale et al. 2000; Caldwell et al. 1970; Ghosh et al. 2018). Comprehending the practical glitches in studying animal behavior, OFT is generally used along with additional investigations such as the elevated plus maze and light-dark box test.

### Conclusion

To summarize, OFT can be used for the assessment of overall locomotor and exploratory activity to detect anxiety in animals.

- Operant Chamber

### Operant Chamber

Lauren Cleland  
Department of Psychology, Texas Christian  
University, Fort Worth, TX, USA

### Synonyms

Operant box; Skinner box

## Definition

An experimental apparatus used in the study of behavior.

## Introduction

An operant chamber is an experimental apparatus commonly used in psychological research with nonhuman animals, such as rats, mice, and pigeons. B.F. Skinner, a psychologist and behaviorist, invented the operant chamber (Skinner 1956). As a result, operant chambers are also referred to as Skinner boxes. Skinner invented the operant box to study operant behavior. Operant behaviors are behaviors that produce a consequence or outcome in the environment, such as positive reinforcement (e.g., food) or negative reinforcement (e.g., escape from shock) (Heron and Skinner 1939). The apparatus was invented in an attempt to increase experimental control over other apparatuses commonly used in the study of learning, such as mazes (Skinner 1957). Within the operant chamber, events can be delivered manually during an experimental session or sessions can be programmed so that all events are automated. This means that experimental variables such as the delivery of consequences are well controlled within an experimental session (Heron and Skinner 1939). In typical experiments using operant chambers, a subject learns to make some response for reinforcement. The operant chamber records when the subject makes the predetermined response. The response is typically a behavior that is easily observed and recorded, as well as easily repeated by the subject without the risk of immediate fatigue. The chamber allows for precise measurements of the frequency with which the subject makes a response. Researchers can use rate of responding to examine the effects of motivational states, reinforcement contingencies, and other manipulations on behavior while attempting to control for all other variables (Skinner 1957).

## Specifications

The operant chamber is typically placed within a sound attenuating cabinet to limit the effect of

any outside noise on the behavior of the subject. Most chambers are ventilated to filter the air and prevent excessive buildup of animal dander within the chamber. Typically, the chamber includes grated flooring for the subject to stand on and move freely about the box. The chamber is often illuminated by a dim light on the roof, which is commonly referred to as a house light. One wall of the chamber houses a food magazine that the subject can easily access. The magazine is capable of delivering reinforcement (e.g., food) to the subject contained within. Objects that can be manipulated such as pull chains, levers, or keys are often contained within the apparatus and serve as response manipulandum. These manipulanda allow for a subject to make multiple responses, allowing the experimenter to collect multiple data points at different times within the experimental session. Operant chambers often include additional components that can serve as stimuli that signal the availability or probability of a consequence or outcome. These stimuli often include lights that can be turned on and off, as well as varied in intensity, and speakers that can emit tones or white noise. Operant chambers may also be capable of delivering shock through the grated flooring. The delivery of these stimuli can be programmed so that their delivery is fully automated (Skinner 1957).

## Operant Cognitive Bias

### ► Judgment Bias

## Operant Conditioning

Federico Sanabria  
Arizona State University, Tempe, AZ, USA

### Synonyms

Instrumental conditioning; Schedules of reinforcement

### Definition

Change in the frequency or probability of a response, caused by a change in the consequence or outcome of that response.

### Introduction

Research on how behavior is shaped by its consequences dates back to Thorndike (1911), who studied how cats and other species learn to escape various enclosures. Skinner (1935) further systematized this research, coining the term *conditioned reflex type I* to refer to responses that occurred because of their consequences. Conditioned reflex was a term used for responses that were conditional on previous experience. Whereas the conditioned reflex type II was dependent on the stimuli that *preceded* the response (commonly known as Pavlovian conditioned stimuli), the conditioned reflex type I was dependent on the stimuli that *followed* the response (the *outcome* of the response). Type I reflexes eventually came to be known as *operant behavior*, and the procedure and process by which they emerge, *operant conditioning*.

Skinner (1935) highlighted the point that, whereas Pavlovian responses to a stimulus (e.g.,

freezing to a tone) change in probability because of the pairing of that stimulus with another stimulus (e.g., tone with footshock), operant responses change in probability because these responses *mediate* the pairing of stimuli. If, for instance, pressing a lever in the presence of the tone resulted in footshock (i.e., lever pressing mediates the tone-footshock pairing), the tone would reduce the probability of pressing a lever.

Skinner investigated operant conditioning in subsequent publications and developed the basic nomenclature and technology for its investigation. Most basic research on operant conditioning is published in the *Journal of the Experimental Analysis of Behavior*, although several other journals have regularly published research on operant conditioning in the last few decades.

Skinner (1953) argued that most behavior, particularly human behavior, is the product of operant conditioning. Although this claim has been challenged, operant conditioning has been demonstrably useful in a wide range of fields. Operant conditioning in animals (typically small rodents and pigeons) is the dominant paradigm for the experimental study of voluntary behavior, including impulsive behavior. The field of behavioral pharmacology relies heavily on operant conditioning models to study the voluntary seeking and self-administration of drugs. Findings from operant conditioning research have been applied to education practices, particularly in populations with learning disabilities, and have informed public policy.

### Key Concepts

#### Experimental Design and Contingency

Operant conditioning involves a *causal relation* between a response-outcome relation (the fact that a specific response produces a specific outcome) and the probability of that response. Therefore, operant conditioning can only be demonstrated experimentally, by manipulating the response-outcome relation (the independent variable) and observing its effect on the probability of the response (the dependent variable).

Operant conditioning is often demonstrated by comparing between conditions in which the outcome is either present or absent. This approach has the limitation of confounding the presence/absence of the outcome with the presence/absence of the response–outcome relation. For instance, the outcome may elicit the response even when it is not caused by that response, such as when a psychostimulant drug elicits a locomotor response. In such situation, the mere removal of the psychostimulant outcome, and not necessarily the locomotion–psychostimulant relation, may reduce locomotion.

The *yoked-control* design prevents this kind of pseudoconditioning (Fig. 1). In this design, a pair of subjects is allowed to produce the target response, but only the response of one subject (the *experimental* subject) produces the outcome for both subjects (experimental and *control* subjects). In other words, both subjects are exposed to the outcome under similar conditions, but only the experimental subject is exposed to the response–outcome relation. Therefore, systematic differences in responding between subjects can only be attributed to the response–outcome relation, thus demonstrating operant conditioning. More technically, the outcome is said to be *contingent* on the response for the experimental subject and *noncontingent* for the control subject. A within-subject yoked-control design, in which a single subject alternates between experimental and

control conditions, may reduce intersubject variability. In this within-subject design, responses in an experimental condition produce the outcomes in both the experimental (contingent) and in the subsequent control (noncontingent) conditions.

### Species and Materials

Operant conditioning is typically conducted in the laboratory, using specialized equipment that allows for strict control of variables. It is most often studied in small laboratory animals, such as rats, mice, and pigeons, because they are easy to house and handle. The prevalence of these species in operant research promoted the development of standard equipment for this research.

The equipment for operant research varies depending on the outcome and species under investigation. The typical apparatus for the study of *rewarding* outcomes was first developed by Skinner and is aptly called the *Skinner box*, or operant chamber. It is a small plastic and aluminum box, furnished with levers or keys (generically called *manipulanda* or *operanda*) to record responses, a device for delivering food outcomes, a houselight, a tone or noise generator, and a grid floor. When the outcome is a drug (primarily in rodents and nonhuman primates), it is often diluted in a solution and delivered through a catheter. The box is typically ventilated and enclosed in a larger, sound-attenuating box.

A common apparatus for the study of *aversive* outcomes in rodents is the active-avoidance shuttle-box. The shuttle-box is similar to the Skinner box, but elongated and lacking levers and food- or drug-delivery devices. The box is divided in two; the floor in each half can be independently electrified to deliver foot-shock. One side (the *shock* side) is sometimes electrified, while the other side (the *safe* side) is not. Operant conditioning is established as movement from the shock side to the safe side (or *shuttling*) when impending foot-shock is signaled.

Operant conditioning has been studied in a wide variety of other species, including humans and nonhuman primates. Unlike work with more typical laboratory animals, operant research with humans and nontraditional species relies on *ad hoc* equipment developed by the investigators.

**Operant Conditioning, Fig. 1** Schematic representation of the yoked-control design. Responses by experimental subjects produce outcomes for both experimental and control subjects. Differences in responding between the experimental and control conditions demonstrate operant conditioning

Human operant research is now typically conducted using videogame-like interfaces for collecting responses, with points exchangeable for goods or money as outcomes. Operant research with nonhuman primates often uses joy-sticks and touchscreen devices, with flavored pellets and juice as outcomes.

### Measuring Behavior

Operant conditioning procedures may be classified as *discrete-trials* and *free-operant* procedures. In discrete-trials procedures, access to a manipulandum is restricted, so that the response can only be emitted once per opportunity. For instance, an animal may be given access to a lever repeatedly, each time for 30 s; a single lever-press removes the lever, infuses a drug intravenously, and terminates the trial. In these procedures, response probability is readily measured as the number of responses emitted per opportunity to respond.

In the free-operant procedure, the manipulandum is continually available. Here the measurement of response probability is less intuitive and involves an indirect measure: the *rate of responding*, which will be signified with the letter *B* (other symbols and abbreviations are included in Table 1). Skinner (1938) proposed *B* as a surrogate for response probability and as the key dependent measure of operant conditioning. *B* is the number of responses produced per unit of time. To estimate response rate over multiple time scales, Ferster and Skinner (1957) proposed the use of the *cumulative record*. This record is obtained from a drum (or cumulative) recorder, in which a pen draws a horizontal line that extends at a constant speed, shifting upwards by a small fixed distance with each response, and resetting once it meets the edge of the drum (Fig. 2). The slope of that line is the response rate over a period of time. If vertical changes in the cumulative record are expressed as the proportion of total responses, the cumulative record is an empirical cumulative distribution function of responses over time. The slope of the cumulative record at any given time is, therefore, an estimate of the probability of a response at that time.

Cumulative records are still used today to track changes in behavior in individual organisms. However, these records are rarely obtained from drum recorders anymore. Instead, the activation of manipulanda is more often recorded electronically, through a computer interface that also controls the stimuli in the experimental environment. In fact, today it is fairly common for a single computer program to control the delivery of stimuli and the recording on responses in a fully automated way for multiple chambers, requiring minimal supervision.

### The Three-Term Contingency

Although the term *reflex* is now rarely used in the context of learning, it still highlights an important feature of operant conditioning: just like reflexes, the operant response occurs in the presence of a stimulus, the *discriminative stimulus*, or  $S^D$ . Prior to training, the rate at which the to-be operant response (e.g., lever pressing) is emitted in the presence of the to-be  $S^D$  (e.g., a light) is called the *operant level* of the response. Once operant conditioning is implemented, the operant response will produce the outcome mostly in the presence of the  $S^D$ . The efficacy of operant conditioning may be measured as the difference between the rate at which the operant response is emitted in the presence of the  $S^D$  and its operant level (albeit with the limitations already discussed). If this difference is positive (because its outcome is rewarding), the  $S^D$  is said to *set the occasion* for the response.

Along with the  $S^D$  (sometimes called the *antecedent*), the operant response (or behavior) and the outcome of that response (or consequence) constitute the *three-term contingency* (Fig. 3). A simple mnemonic to remember the components of the three-term contingency uses their first letters: Antecedent, Behavior, and Consequence, or ABC. The term *contingency* refers to the rules by which operant conditioning is implemented. The three-term contingency is the general rule that in the presence of  $S^D$  A, response B will produce outcome C.

The operant response is typically defined not in terms of the movements involved in the response, but in terms of its effect on the environment.

**Operant Conditioning, Table 1** Symbols and abbreviations

| Symbol/abbreviation               | Meaning                                                                              |

| <i>n</i>                          | Mean ratio requirement                                                               |
| <i>t</i>                          | Mean interval requirement                                                            |
| <i>r</i>                          | Rate of reinforcement                                                                |
| COD                               | Changeover delay                                                                     |
| <i>Matching law parameters</i>    |                                                                                      |
| <i>b</i>                          | Choice bias                                                                          |
| <i>s</i>                          | Sensitivity of choice to relative rate of reinforcement ( $r_1/r_2$ )                |

For instance, *lever pressing* is typically defined as the closure of a microswitch in the back of the lever. The lever-pressing *operant* does not indicate how the microswitch is closed, whether it is by pressing the lever with a paw or nose. The operant is not a single response, but a *class* of responses that share an effect on the environment. At any given time, the operant can only take one of two values: it either occurs (the micro-switch is closed) or it does not (the microswitch is open). In contrast, the particular action that results in the

operant, called the *topography* of the operant response, may take many forms.

A stimulus in the presence of which the operant does *not* result in the outcome is called the  $S^\Delta$  (*S-delta*). The operant is called a *discriminated operant* when *B* varies depending on whether the  $S^D$  or the  $S^\Delta$  is present. Under appropriate conditions, the discriminated operant may serve as evidence that the organism has the sensory capacity to detect the difference between the  $S^D$  and the  $S^\Delta$ .

**Operant Conditioning, Fig. 3** Schematic representation of the three-term contingency of operant conditioning

### Interaction with Other Learning Processes

The three-term contingency highlights some associative and nonassociative processes that may facilitate or hinder operant conditioning. Two processes are particularly informative of the structure of operant conditioning: outcome-related sensitization and habituation, and  $S^D$ -outcome association learning.

The unconditioned response to a stimulus may change merely because of the repeated presentation of that stimulus: a reflex, for instance, may become stronger (sensitization) or weaker (habituation) with repeated elicitation, even without muscle fatigue or sensory adaptation. It is in principle possible that the repeated presentation of the outcome sensitizes the ostensive operant (see the locomotion-psychostimulant example in the *Experimental design and contingency* section) or that it habituates a response that interferes with the operant (e.g., a neophobic response to food). There is evidence suggesting that the rewarding properties of an outcome may also sensitize and habituate (McSweeney and Murphy 2009).

Operant conditioning also implies a potential Pavlovian association between the  $S^D$  (or any other contextual stimuli) and the outcome of the operant response. For instance, a tone that sets the occasion for lever pressing for food may become a Pavlovian conditioned stimulus associated with the food. The conditioned response to the  $S^D$  may facilitate or suppress the operant. For instance, if the  $S^D$  is separately associated with food, the presence of the  $S^D$  would increase the rate at which a lever that yields food is pressed – this is an example of *Pavlovian-instrumental transfer*. In contrast, when food is programmed for a raccoon for depositing a coin into an enclosure, the coin-food association elicits instead a coin-rubbing response – this is an example of instinctive drift (Breland and Breland 1961).

### Reinforcement and Punishment

In operant conditioning, the outcome of the response may increase or reduce  $B$ . If the outcome increases  $B$ , it is called a *reinforcer*; if the outcome

reduces  $B$ , it is called a *punisher*. Reinforcement and punishment are thus defined by the change that the outcome causes on  $B$ .

The reinforcing or punishing outcome may be the introduction of a stimulus or the removal of a stimulus. Figure 4 shows the classification of operant procedures in terms of the nature of the outcome (introduction versus removal) and its effect on response rate (increase versus reduction). The procedures that involve the introduction of stimuli are fairly straightforward: the response produces an stimulus that is either rewarding and increases the rate of that response (*positive reinforcement*) or is aversive and reduces the rate of that response (*positive punishment* or simply *punishment*). The former stimulus is signified as  $S^{r+}$  (reinforcer); the latter is signified as  $S^{p+}$  (punisher). Increased lever pressing because it leads to food is an example of positive reinforcement, where food is the  $S^{r+}$ . Reduced lever pressing because it leads to foot-shock is an example of punishment, where foot-shock is the  $S^{p+}$ .

The procedures that involve the removal of a stimulus are less intuitive. In *negative reinforcement*, the outcome of a response is the removal of an aversive stimulus,  $S^{r-}$ , which increases  $B$ . The  $S^{r-}$  may be removed *after* its onset, such as when the rat shuttles to the safe side, of the shuttle-box when foot-shock (the  $S^{r-}$ ) is delivered. Such procedure is called an *escape* or *passive avoidance* procedure. Alternatively, the  $S^{r-}$  may be removed *before* its onset, such as when a stimulus preceding foot-shock elicits a shuttling response to the safe side. Such procedure, in which the  $S^{r-}$  may be prevented, is called an *active avoidance* procedure.

In *negative punishment*, the outcome of a response is the removal of a rewarding stimulus,

$S^{p-}$ , which reduces  $B$ . Negative punishment is a common procedure for reducing undesired behavior, such as acting out, in children. In that situation, the undesired behavior is the response that removes a rewarding  $S^{p-}$  (e.g., access to a preferred toy), thus reducing the rate of the undesired behavior. This example highlights the relative nature of reinforcement and punishment: negative punishment of a behavior is often described as the reinforcement of the omission of that behavior, or the differential reinforcement of other behavior (DRO).

Although operant conditioning may involve any of the cells in the matrix of Fig. 4, most variations in implementation and their effects on behavior have involved the top-left cell, positive reinforcement. The remaining sections will, therefore, focus on research on this procedure.

## Simple Schedules of Reinforcement

### Contingencies of Reinforcement

The rules by which a response produces a  $S^{r+}$  are called the *contingencies of reinforcement*. Contingencies of reinforcement may be thought of as models of naturally occurring positive feedback loops between behavior and environment (e.g., between foraging behavior and prey obtained), or as techniques to promote behavior (e.g., engaging in appropriate play behavior).

The simplest contingency of reinforcement is called *continuous reinforcement*, or CRF: every instance of the response is reinforced. Another way of stating this is that  $p(S^{r+} | \text{response}) = 1.0$  (the probability of the reinforcer given the response is 1.0). In contradistinction to CRF, in *intermittent reinforcement* only some

|               | Introduces Stimulus                                 | Removes Stimulus                                  |
|---------------|-----------------------------------------------------|---------------------------------------------------|
| Increases $B$ | Positive Reinforcement<br>[ $S^{r+}$ is appetitive] | Negative Reinforcement<br>[ $S^{r-}$ is aversive] |
| Reduces $B$   | Positive Punishment<br>[ $S^{p+}$ is aversive]      | Negative Punishment<br>[ $S^{p-}$ is appetitive]  |

**Operant Conditioning, Fig. 4** Classification of operant procedures in terms of the nature of the outcome (*introduces* versus *removes* a stimulus) and its impact on rate of responding (increases versus reduces  $B$ )

instances of the response are reinforced, so  $0.0 < p(S^{r+}|\text{response}) < 1.0$ . Whereas CRF can be implemented only in one way, intermittent reinforcement may be implemented in a virtually infinite number of ways. This section reviews the most frequently studied contingencies of intermittent reinforcement, most of them first introduced by Ferster and Skinner (1957). These schedules are arranged as a matrix in Fig. 5. All schedules are described in terms of responses and time; in all schedules, responses only count and time only passes while the  $S^D$  is present.

### Ratio Schedules

In *ratio* schedules of reinforcement, the reinforcer is contingent on emitting a number of responses since the last reinforcer. This number of responses is called the *ratio requirement*, and it may be fixed or variable (Fig. 5, top row). In *fixed-ratio* (or FR) schedules, the ratio requirement does not change between reinforcer deliveries. For instance, a rat may be repeatedly required to press a lever 5 times to obtain a reinforcer. In this case, the schedule is referred to as FR 5. More generally, an FR schedule is referred to as FR  $n$ , where  $n$  is the ratio requirement. Note that CRF is an FR schedule with  $n = 1$ , or FR 1. The FR schedule is akin to piecework, where the worker is paid per unit completed – each unit completed is the response, payment is the reinforcer, and the piece rate is the reciprocal of the ratio requirement.

Fixed-ratio schedules of reinforcement are widely used in behavioral economics. In this context, the FR requirement ( $n$ ) constitutes the *unit price*; the number of  $S^{r+}$  obtained constitutes the *demand* for  $S^{r+}$ . The function that relates the demand for  $S^{r+}$  to  $n$  is the *demand curve* for the  $S^{r+}$ . The slope of the demand curve is the *elasticity*

of the demand for  $S^{r+}$ , the sensitivity of demand to changes in  $n$ . The slope of the demand is typically negative; when it is steep, the demand for  $S^{r+}$  is *elastic* (sensitive to  $n$ ); when it is flat, the demand for  $S^{r+}$  is *inelastic* (insensitive to  $n$ ). Quantitative models of demand elasticity have informed key concepts in behavioral economics – particularly in the context of drug reinforcement – such as the essential value of reinforcers (Hursh and Silberberg 2008).

In *variable-ratio* (or VR) schedules, the ratio requirement changes randomly between reinforcer deliveries. For instance, a rat may be required to press a lever twice to obtain one reinforcer, but 8 times to obtain the next one, 5 times to obtain the one after that, and so on. A VR schedule is referred to as VR  $n$ , where  $n$  is the *mean* ratio requirement. There are several ways to implement VR schedules. For instance, a list may be made of equally spaced numbers with mean  $n$ ; after each reinforcer, a number is randomly sampled from the list, with or without replacement, and that number is the next ratio requirement. In this method, the probability of reinforcement given  $x$  responses since the last reinforcer,  $p(S^{r+}|x)$ , increases with  $x$ . Often times investigators prefer to keep  $p(S^{r+}|x)$  constant over  $x$ . To arrange for that, investigators rely on *random-ratio* (or RR) schedules of reinforcement, in which a computer samples a probability gate after each response, reinforcing it with probability  $p$ . The mean requirement of the RR schedule is  $n = 1/p$ . The main limitation of RR schedules is that they may yield very large ratio requirements, which may not support behavior. Variable- and random-ratio schedules are akin to slot machines, where each pull of the lever (or push of the button) yields a payoff probabilistically – pulling the lever is the response, the payoff is the  $S^{r+}$ , and the pay rate is the reciprocal of the mean ratio requirement.

Another ratio schedule commonly used in research is the *progressive-ratio* (or PR) schedule. In PR schedules, the ratio requirement increases over consecutive reinforcers, resetting between sessions either completely or partially. The first ratio requirement is typically very low, and the following requirements are often programmed to

|          | Fixed               | Variable               |
|----------|---------------------|------------------------|
| Ratio    | Fixed Ratio (FR)    | Variable Ratio (VR)    |
| Interval | Fixed Interval (FI) | Variable Interval (VI) |

**Operant Conditioning, Fig. 5** Simple schedules of reinforcement classified according to whether its requirement is a number of responses (Ratio) or the first response after an interval (Interval), and whether the requirement is the same (Fixed) or not (Variable) between reinforcers

increase geometrically (e.g., 8, 12, 18, 27), although arithmetic progressions of fixed step-size (e.g., 8, 12, 16, 20) and other progressions are fairly common. The key dependent measure in PR schedules is the *breakpoint* – the highest ratio requirement completed before the subject stops responding for a long period of time. The breakpoint is often used as a measure of the efficacy of the reinforcer (Hodos 1961).

### Interval Schedules

In *interval* schedules of reinforcement,  $S^{+}$  is contingent on emitting one response after some time since the last reinforcer. The time during which  $S^{+}$  is not available is called the *interval requirement* and is never signaled (if it were, the signal would constitute an  $S^{\Delta}$ ). Responses prior to the completion of the interval requirement are not reinforced. Like ratio requirements, interval requirements may be fixed or variable (Fig. 5, bottom row). In *fixed-interval* (or FI) schedules, the interval requirement does not change between reinforcers. For instance, a rat may be required to make one lever press after 3 min has elapsed since the last reinforcer to obtain the next reinforcer. In this case, the schedule is referred to as FI 3-min. More generally, an FI schedule is referred to as FI  $t$ , where  $t$  is the interval requirement. The FI schedule is akin to baking a cake that takes 45 min to be done: checking the cake before 45 min elapse has no effect (in terms of producing an edible cake), only checking it after 45 min is reinforced with an edible cake.

In the cake-baking example, however, waiting too long (e.g., 90 min) probably results in a ruined cake. Such constraint on the availability of the reinforcer may be incorporated to an FI schedule in the form of a *limited hold* or LH. The LH defines a maximum time after the interval requirement is completed during which the reinforcer is available. In the cake example, if the cake were ruined after 50 min in the oven, the edible cake would reinforce the checking on a FI 45-min LH 5-min schedule. Because of such short LH relative to the FI schedule, or simply because cake is typically preferred sooner rather than later, most people use a kitchen timer when baking a cake. The prevalent use of such external timers highlights the utility of FI

performance, without external timers, in assessing the intrinsic capacity of organisms to track the passage of time (Daniels and Sanabria 2017).

In *variable-interval* (or VI) schedules, the interval requirement changes between reinforcers. For instance, a rat may be required to make one lever press after 5 min to obtain one reinforcer, then after 1 min to obtain the next one, then after 3 min to obtain the one after that, and so on. A VI schedule is referred to as VI  $t$ , where  $t$  is the mean interval requirement. Like VR schedules, there are several ways to implement VI schedules. For instance, a list may be made of equally spaced times with mean  $t$ ; after each reinforcer, a time is randomly sampled from the list, with or without replacement, and that time is the next interval requirement. Nonetheless, in this method,  $p(S^{+}|t)$  increases with  $t$ .

There are two prevalent methods to keep  $p(S^{+}|t)$  approximately constant. The first one is to implement a *random-interval* (or RI) schedule. In this schedule, the computer samples a probability gate after every interval  $\tau$ , where  $\tau$  is typically short and fixed (e.g., 1 s), and completes the interval requirement with probability  $p$ . The mean interval requirement of the RI schedule is  $t = \tau/p$ . The main limitation of RI schedules is that they may yield very long interval requirements, which may not support behavior. The second method prevents very long intervals by setting up a list of times with mean  $t$ , on the basis of a progression of times where longer times are more spaced. After each reinforcer, a time is randomly sampled from the progression, with or without replacement, and that time is the next ratio requirement. Fleshler and Hoffman (1962) devised an equation for the precise length of consecutive times in this progression, so that the distribution of sampled times approximate the exponential distribution expected from a constant  $p(S^{+}|t)$ .

Variable- and random-interval schedules are akin to the delivery of interesting posts on your Facebook news feed. Checking the news feed has no effect on seeing an interesting post until an interesting post is posted (which happens at unpredictable times); once the interesting post is posted, checking the news feed results in seeing

an interesting post, which reinforces checking the news feed.

### Other Simple Schedules

There are other important schedules of reinforcement that do not fit into the matrix of Fig. 5. The *differential reinforcement of low rates* (DRL) schedule is usually implemented to train a slower pace of responding and to assess the capacity to withhold a reinforced response (e.g., Sanabria and Killeen 2008). In this schedule, reinforcement is contingent on an interval between consecutive responses (inter-response time, or IRT) longer than a criterion (e.g., 6 s); shorter IRTs are not reinforced. Like in FI schedules, a LH may be implemented in DRL, such that IRTs that are longer than the LH are not reinforced. The *differential reinforcement of high rates* (DRH) schedule is the opposite of DRL; it is often implemented to train a faster pace of responding. In this schedule, reinforcement is contingent on IRTs shorter than a criterion; longer IRTs are not reinforced.

Often times, performance at operant level contains too few responses that may be reinforced according to some schedule. For instance, a pigeon may rarely produce two consecutive pecks that are less than 300 ms apart, making it difficult for it to perform in a DRH 300-ms schedule any different than at operant level. In such cases, behavior may be put in contact with the contingencies of reinforcement through a *shaping* procedure. Shaping involves reinforcing successive approximations to a goal response, while discontinuing reinforcement of intermediate behaviors that are already acquired. There are many ways of shaping a response, but a particularly systematic one is the *percentile* schedule of reinforcement (Galbicka 1994). In this schedule, reinforcement is contingent upon a quantifiable dimension of behavior being either above or below some criterion established on the basis of recent performance. The pigeon in the previous example, for instance, may be trained on a percentile DRH schedule that only reinforces IRTs shorter than the median of the last 15 IRTs. This is expected to progressively reduce IRTs toward the 300-ms goal.

### Noncontingent Reinforcement, Induction, and Extinction

There are two response-stimulus arrangements that, although not strictly schedules of reinforcement (because no reinforcement is scheduled), they are often discussed in relation to schedules of reinforcement. These are *noncontingent reinforcement* (or NCR) and *extinction*.

NCR consists of presenting an otherwise contingent reinforcer in a noncontingent way. The yoked-control condition (bottom of Fig. 1) is an example of NCR, because the stimulus that serves as  $S^{r+}$  in the experimental condition is presented regardless of performance in the yoked-control condition. NCR is often implemented as *time* schedules of reinforcement. Time schedules are similar to interval schedules, except that once the interval requirement is completed, the  $S^{r+}$  is delivered whether responding occurs or not. Like interval schedules, time schedules can be fixed (FT) or variable (VT).

The terms “noncontingent reinforcement” and “time schedules of reinforcement” are somewhat oxymoronic. If the  $S^{r+}$  is noncontingent, by definition, it cannot serve as  $S^{r+}$ . Also, time schedules do not schedule  $S^{r+}$ , because the scheduled stimulus, rewarding as it may be, is noncontingent. There are, however, two reasons why this terminology has persisted. The first one is that NCR and time schedules are typically implemented to compare performance in these schedules relative to schedules in which the noncontingent  $S^{r+}$  is contingent. This is the case, for instance, in the yoked-control use of NCR. The second reason stems from an equivocal use of the term *reinforcement*. As defined here, operant reinforcement is the increase in the rate ( $B$ ) of the response *that produces* the  $S^{r+}$ . Reinforcement also increases behavior other than the operant through various mechanisms (e.g., unconditioned effects, context-outcome associations). These behaviors are not reinforced, they are *induced*. However, it is unclear whether or not the mechanisms that subserve induction overlap with those that subserve reinforcement. Some theories suggest, for instance, that induction and reinforcement depend on a single mechanism: the temporal proximity between behavior and  $S^{r+}$  (Skinner 1948). These

theories blur the distinction between induction and reinforcement – furthermore, they blur the distinction between procedure (reinforcement) and process (temporal contiguity). In that context, reinforcement can be noncontingent (Killeen and Pellón 2013).

Whereas NCR precludes reinforcement by removing the response- $S^{r+}$  contingency, extinction precludes reinforcement by removing  $S^{r+}$  altogether. Extinction is typically implemented following a schedule of reinforcement and without removing the  $S^D$ . Because prior to extinction  $S^{r+}$  maintained the operant, the removal of  $S^{r+}$  must result in a decline in  $B$ . Extinction thus implies a decline in  $B$  due to the removal of the  $S^{r+}$  that maintained  $B$ .

Recovery of an extinguished response can occur with relative ease after discontinuing the  $S^D$  (*spontaneous recovery*), changing it (*renewal*), extinguishing another response (*resurgence*), or implementing NCR (*reinstatement*). The fragility of extinction performance has informed theories of extinction learning that are crucial to understand the persistence of undesired behaviors (Bouton and Todd 2014).

### Schedule Control and Feedback Functions

Schedules of reinforcement vary substantially in their effect on behavior, as shown in the

cumulative records in Fig. 6. In FR schedules, responding between reinforcers typically consists of a *postreinforcement pause* (also called *pre-ratio pause*, or *latency to first response*) followed by a steady stream of responses (the *ratio run*). Similar performance is observed in FI schedules, but under some conditions the transition from pause to responding appears to be less abrupt; this pattern is called the *FI scallop*. Behavior in VR and VI (and RR and RI) schedules is typically more evenly distributed across the inter-reinforcer interval than in FR and FI schedules, but VR schedules maintain a higher  $B$  (steeper cumulative records) than VI schedules.

All else being equal, the systematic change in the pattern of responding – length of postreinforcement pause, curvature of scallop, response rate, etc. – as a function of schedule of reinforcement is called *schedule control*. To demonstrate schedule control, experimental and control training should be similar in every aspect, including rate of reinforcement ( $r$ ), except in the effective schedule of reinforcement.  $r$  is maintained invariant across conditions by yoking it. For instance, Catania et al. (1977) yoked  $r$  in VI and VR schedules by setting up the interval requirement in the VI-schedule condition to the observed inter-reinforcer interval in the VR-schedule condition.  $B$  was higher in VR than in yoked-VI schedules, indicating that response rate was under schedule

**Operant Conditioning, Fig. 6** Illustrative cumulative records for FR 10, FI 20-s, VR 10, and VI 15-s

control. This difference in  $B$  across ratio and interval schedules has motivated much theorizing on schedule control (e.g., Peele et al. 1984).

Operant conditioning research often relies on VI and RI schedules for two reasons. First, unlike FR and FI schedules, VI and RI schedules yield relatively steady streams of responding continuously (Fig. 6, rightmost record). Second, unlike ratio schedules, interval schedules allow adequate experimental control over the rate at which reinforcers are delivered,  $r$ . In ratio schedules, the investigator cannot fully control  $r$ , because it varies linearly with  $B$  (mathematically,  $r = B/n$ ). In interval schedules, an investigator can have fairly good control over  $r$ , because it reaches a flat maximum even with a modest  $B$ .

The relation between  $B$  and  $r$  in a schedule may be represented graphically as a *feedback function*. As the feedback functions in Fig. 7 show, the slope of the ratio feedback function is the reciprocal of the ratio requirement ( $n$ ), the asymptote of the interval and time feedback functions is the reciprocal of the interval requirement ( $t$ ), and  $r = 0$  in extinction. Interval and time schedules differ noticeably on  $r$  only when  $B$  is very low.

### Compound Schedules of Reinforcement

The schedules of reinforcement described so far model relatively simple relations between behavior and environment. More complex relations

may be modeled by combining simple schedules. These combinations are called *compound schedules of reinforcement*. The *components* of a compound schedule – the simple schedules that make up the compound schedule – may be presented alternatively or simultaneously. Components may be implemented on different manipulanda (*heterogeneous* compound schedules) or on the same manipulandum (*homogeneous* compound schedules).

### Multiple and Mixed Schedules: Stimulus and Schedule Control

Components of a compound schedule may alternate on the basis of the passage of time. For instance, VI schedules with different interval requirements may alternate every 5 min on average. When a different  $S^D$  signals each alternating component (e.g., the color of the keys indicate the VI schedule in effect), the compound schedule is called a *multiple* schedule of reinforcement.

Multiple schedules may be used to establish and evaluate stimulus control. For instance, a higher  $B$  in the VR than in the extinction component of a multiple schedule would demonstrate that the  $S^D$  have gained control over performance. To distinguish stimulus control from schedule control, however, performance must be tested using the same schedule (same  $r$ , typically extinction) in the presence of each  $S^D$ .

When alternating components are not differentially signaled, the compound schedule is called

**Operant Conditioning, Fig. 7** Feedback functions for ratio (left panel), interval (central panel), and time schedules, and for extinction (right panel). The functions trace

changes in the rate of reinforcement ( $r$ ) with changes of rate of responding ( $B$ )

a *mixed* schedule of reinforcement. Unlike multiple schedules, in mixed schedules there is no  $S^D$  to potentially gain control over performance. Changes in  $B$  across components of a mixed schedule can only be due to the either (a) the passage of time in a component, if components alternate at fixed times, or (b) the difference in the contingencies of reinforcement across components (schedule control).

### Chained and Tandem Schedules: Conditioned Reinforcement

Components of a compound schedule may also alternate when they are completed. In these schedules, completion of the first component – called the *initial link* – is reinforced only with the transition to a second component and that second component may be reinforced with the transition to a third component, and so on. The last component in the schedule – called the *terminal link* – is reinforced with the *primary* reinforcer. The primary reinforcer is defined by its capacity to reinforce a response regardless to its relation to other reinforcers – food for a hungry animal, water for a thirsty animal, access to a conspecific, some drugs of abuse, among many others, constitute primary reinforcers.

Compound schedules of reinforcement in which a different  $S^D$  signals each link are called *chained* schedules. As in multiple schedules, the  $S^D$  of chained schedules may gain control over performance. More importantly, each  $S^D$  in a chained schedule may serve as a *conditioned* (or *secondary*) reinforcer for responding in the just-preceding link. A conditioned reinforcer reinforces an operant conditionally on some relation to another reinforcer. Secondary reinforcement is demonstrated to the extent that (a)  $B$  increases when access to the reinforcing  $S^D$  is contingent on the response, but not when it is noncontingent, and (b) this difference is reduced when the relation between  $S^D$  and the primary reinforcer is removed. A typical example of a conditioned reinforcer is money. An individual may work to obtain money (initial link) and then may spend that money on various goods (terminal link). Money constitutes a conditioned reinforcer for work to the extent that noncontingent money

(e.g., cash gifts) reduces work, and that a weaker relation between money and goods (e.g., inflation) reduces the impact of noncontingent money on work (e.g., an individual does not work less because of a cash gift in a currency she does not use).

The demonstration of conditioned reinforcement in chained schedules is challenging, because it involves isolating the primary-reinforcing effects of the terminal  $S^{r+}$  on responding that occurs in preceding links. For example, in a chained VI FR schedule of food reinforcement, food produced by the terminal FR link is contingent upon responding on the initial VI link; without those responses, neither the FR link nor the food reinforcer would occur. To the extent that such contingency increases VI responding, food serves as a primary reinforcer of VI responding. In general, responding on any link in a chained schedule may be a function of conditioned reinforcement (from subsequent links) and primary reinforcement (from the terminal  $S^{r+}$ ).

*Tandem* schedules of reinforcement may be used to isolate primary-reinforcer effects on the initial link of a compound schedule. Tandem schedules are similar to chained schedules, but no differential  $S^D$  signals each link. Therefore, in tandem schedules, there is no terminal-link  $S^D$  that reinforces initial-link responses; the only reinforcer operating is the primary reinforcer, i.e., the terminal  $S^{r+}$ . All other things being equal, then, differences in performance during initial links in chained versus tandem schedules are due to the conditioned-reinforcing effects of terminal links in the chained schedule (control conditions may be strengthened by noncontingent alternation of the  $S^D$  in the tandem schedule, yoked to the contingent alternation in the chained schedule).

## Choice Behavior

### Concurrent Schedules

A type of compound schedule, the *concurrent* schedule of reinforcement, has been so extensively studied that it merits its own section. In concurrent schedules, two or more schedules

operate simultaneously and independently of each other (often times they are referred to as *independent concurrent* schedules).

Concurrent schedules are often used in operant research to model a key aspect of natural environments – that they typically contain more than one schedule of reinforcement, each operating independently of others, and each supporting mutually inconsistent behavior. While a paycheck may reinforce working behavior, other stimuli are available to reinforce leisure behavior. Even in the operant chamber, lever pressing may be reinforced for food, but exploratory behavior away from the lever may yield its own reinforcers. In that sense, even simple schedules of reinforcement may be thought of as concurrent schedules, where responses on only one schedule are measured (Herrnstein 1970).

For over 50 years, research on choice behavior has relied heavily on concurrent schedules of reinforcement. In particular, concurrent VI VI schedules have been extensively used because they afford experimental control over a key independent measure, the *relative rate of reinforcement*, which is the ratio of reinforcers obtained from each component of the concurrent schedule ( $r_1/r_2$ ). In this research, the effect of  $r_1/r_2$  is measured on the *relative rate of responding* ( $B_1/B_2$ ), which is the ratio of responses allocated to each component of the concurrent schedule;  $B_1/B_2$  is the principal measure of choice. Concurrent VI VI

schedules attain control over  $r_1/r_2$  because this ratio depends primarily on the interval requirements (programmed by the experimenter) and substantially less so on  $B_1/B_2$  (emitted by the organism). This invariance (and its limits) is evident when feedback functions akin to those in Fig. 7 are constructed for concurrent VI VI schedules, but using relative – instead of absolute – measures of responding and reinforcement (Fig. 8).  $r_1/r_2$  diverges from the reciprocal of the ratio of interval requirements ( $t_2/t_1$ ) only when response allocation is extreme (very low or very high  $B_1/B_2$ ).

Other concurrent schedules do not provide the level of control over  $r_1/r_2$  shown in Fig. 8. For instance, in concurrent ratio schedules,  $r_1/r_2$  increases with more responses on components with lower requirements ( $n$ ), because of the linear relation between  $r$  and  $B$  in simple ratio schedules (Fig. 7). Concurrent ratio schedules may approximate the feedback function of Fig. 8 by scheduling them as *dependent* (or *nonindependent*) concurrent schedules (Stubbs and Pliskoff 1969). In these schedules, only one of the components is effective at any given time; the effective schedule is selected randomly after each reinforcer and is not signaled. Under these conditions,  $r_1/r_2$  may be controlled through the relative frequency of each component. Dependent scheduling is also useful to further reduce the small discrepancies between

### Operant Conditioning,

**Fig. 8** Feedback function, in log-log scale, for concurrent VI 30-s VI 30-s ( $t_2/t_1 = 1$ ) and concurrent VI 30-s VI 300-s ( $t_2/t_1 = 10$ );  $t_2/t_1$  is indicated with dashed lines. The continuous lines trace the relative rate of reinforcement ( $r_1/r_2$ ) as a function of relative rate of responding ( $B_1/B_2$ ). Over a broad range of  $B_1/B_2$  (from roughly 1/1000 to 1000),  $r_1/r_2 \approx t_2/t_1$

$r_1/r_2$  and  $t_2/t_1$  in concurrent VI VI schedules (Fig. 8). In dependent concurrent VI VI schedules, extreme relative response rates are not reinforced (because the preferred component is sometimes not effective) and are therefore discouraged.

An important variable in (independent) concurrent VI VI schedules is the cost of switching over from one component to another. This is typically implemented as a short interval ( $< 5$  s) during which the switched-to component is ineffective. This interval is called the *changeover delay* (COD); it starts either on the last response before or the first response after switching over. When concurrent VI VI schedules serve as models of foraging, where each component represents a patch of prey, the COD represents the time it takes to travel between patches (Dow and Lea 1987).

In order to facilitate rigorous experimental control over the COD and other switching contingencies, Findley (1958) developed an alternative implementation of independent concurrent schedules. Whereas the components of concurrent schedules are typically implemented in separate manipulanda, the *Findley procedure* arranges all components on a *main* manipulandum, each signaled by a different  $S^D$ , while responses to a *changeover* manipulandum change the effective schedule in the main manipulandum. In the Findley procedure, switching contingencies can be scheduled in the changeover manipulandum. For example, to implement a 5-s COD, an FI 5-s may be scheduled in the changeover manipulandum.

## The Matching Law

Regardless of its implementation (independently or dependently, two-manipulanda or Findley procedure), concurrent VI VI performance regularly shows that  $B_1/B_2$  is a power function of  $r_1/r_2$ ,

$$\frac{B_1}{B_2} = b \left( \frac{r_1}{r_2} \right)^s. \quad (1)$$

This equation is known as the *generalized matching law* (Baum 1974). When  $b = s = 1$ , Eq. 1 becomes a simple identity between  $B_1/B_2$  and  $r_1/r_2$ , a relation known as *strict matching*. In a plot relating  $B_1/B_2$  to  $r_1/r_2$  in log-log space (which linearizes Eq. 1), strict matching appears as an identity line (Fig. 9).

Parameter  $b$  in Eq. 1 is indicative of choice *bias*. If  $b > 1$ , component 1 is chosen more than expected from strict matching; if  $b < 1$ , component 2 is chosen more than expected from strict matching. It is as if  $B_1/B_2$  strictly matched  $r_1/r_2$ , but the preferred component provided additional reinforcers that are not measured. In a matching plot, choice bias appears as  $B_1/B_2$  when  $r_1/r_2 = 1$  (Fig. 9, dashed lines).

Parameter  $s$  is indicative of choice *sensitivity* to relative rate of reinforcement. If  $s > 1$ ,  $B_1/B_2$  changes faster with  $r_1/r_2$  than expected from strict matching; this is called *overmatching*. If  $s < 1$ ,  $B_1/B_2$  changes slower with  $r_1/r_2$  than expected from strict matching; this is called *undermatching*. In a matching plot, choice sensitivity appears as the slope of the function (Fig. 9). Steeper functions are indicative of overmatching,

## Operant Conditioning,

**Fig. 9** Traces of the matching law (Eq. 1). Left panel:  $s = 1$  and  $b = 0.5$  (bottom), 1.0 (middle: identity line), and 2.0 (top). Right panel:  $b = 1$  and  $s = 0.6$  (flatter), 1.0 (diagonal: identity line), and 1.4 (steeper). Note that these plots are similar to the feedback function of Fig. 8, but with the axes flipped

whereas flatter functions are indicative of undermatching. In concurrent VI VI performance, undermatching is more common than overmatching and is exacerbated by short or absent CODs (Davison and McCarthy 1988).

Reinforcers may differ between components of concurrent VI VI schedules not just in their rate, but also in their amount, quality, delay, etc. Larger, better, more immediate, and, in general, more efficacious  $S^{r+}$  in component 1 appear to increase  $B_1/B_2$  gradually. It thus appears that  $B_1/B_2$  is sensitive to a common factor across these dimensions: *value*. The outcome of one component is more valuable if it involves more frequent, larger, or more immediate  $S^{r+}$ .  $B_1/B_2$  in concurrent VI VI schedules may provide an objective measure of relative value of outcomes, such as brands of a product or opportunities to mate. Such feature has had important implications for behavioral economics and foraging theory (Herrnstein 1997).

Herrnstein (1970) also developed a key implication of the matching law for simple schedules of reinforcement. Behavior in a simple schedule may be thought of as a choice between the operant ( $B_1$ ) and every other behavior that is inconsistent with the operant ( $B_0$ ). The operant and every other behavior that is not the operant constitute the totality of behavior and that totality is a constant:  $B_1 + B_0 = k$ . It may be assumed that, whereas the operant is reinforced by the schedule at a rate  $r_1$ , inconsistent behavior is reinforced by an implicit schedule at rate  $r_0$ . When these assumptions are incorporated into Eq. 1 with  $b = s = 1$ , and it is solved for  $B_1$ ,

$$B_1 = \frac{kr_1}{r_1 + r_0}. \quad (2)$$

Equation 2 is called the *quantitative law of effect*. Assuming a constant implicit rate of reinforcement ( $r_0$ ), it predicts that response rate on a simple schedule ( $B_1$ ) increases fast as rate of reinforcement ( $r_1$ ) increases from zero, but it increases more slowly and toward an asymptote of  $k$  as  $r_1$  becomes very large. Aside from its quantitative predictions of simple-schedule performance, the quantitative law of effect has substantial implications for a theory of reinforcement. For instance,

it predicts that a response is reinforced not only by increasing the rate at which reinforcers are produced, but also by decreasing the rate at which other behaviors are reinforced (or induced). From this perspective, reinforcement is thought not as strengthening or energizing the reinforced behavior, but as shaping the allocation of a limited resource – time or responses – among alternatives.

### Concurrent-Chains Schedules: Choosing Between Schedules

Relative response rates may appear to index the preference of the organism for the components of a concurrent schedule. However, schedule control exerted by each component and global-maximization contingencies are likely to interfere with the expression of preference for that component. For example, in a concurrent VR 100 FI 30-s, an organism is likely to make most responses on the VR schedule and only visit the FI schedule around 30 s since the last reinforcer. This pattern of behavior may emerge because VR schedules maintain a steady and high  $B$  (Catania et al. 1977), whereas FI responding clusters around the interval requirement, and also because this pattern maximizes the global rate of reinforcement ( $r_1 + r_2$ ). Regardless of the cause, it does not seem reasonable to infer, from concurrent-schedule performance, which component the organism would stick to if it had to choose between them.

Choice between schedules of reinforcement is studied using *concurrent-chains* schedules. These schedules are similar to normal chained schedules, but the initial link is a concurrent schedule instead of a simple schedule. The components of the initial link do not yield a primary reinforcer, but instead each yields access to another simple schedule – the terminal link – signaled by a different  $S^D$ . Another way to describe concurrent-chains schedules is as concurrent schedules in which each component is reinforced with access to a simple schedule. Following a similar rationale as in concurrent schedules, the initial link of concurrent-chains schedules is typically a concurrent VI VI schedule with equal interval requirements. If  $B_1/B_2$  in concurrent VI VI schedules

measures the relative value of the outcome of each component, then  $B_1/B_2$  in the initial-link, equal-requirement VI VI of a concurrent-chains schedule measures the relative value of the schedules in the terminal link. Consider, for instance, a concurrent-chains schedule in which the initial link is VI 60-s VI 60-s and the terminal link is either VR 100 or FI 30-s. If twice the responses are allocated to the VI 60-s reinforced with the VR 100 than to the VI 60-s reinforced with the FI 30-s ( $B_1/B_2 = 2$ ), it may be inferred that the VR 100 schedule is twice as valuable as the FI 30-s schedule.

## Operant Conditioning and the Science of Behavior

### Complex Behavior

In concurrent-chains schedules, two forms of schedule compounding, chained and concurrent schedules, are themselves compounded. Such higher-order compounding highlights the unlimited number of ways in which simple and compound schedules may be further compounded and modified to model complex operant behavior. Indeed, one approach to complex cognition and social learning involves conceptualizing these processes as complex operant behavior.

One example of an operant approach to complex cognition involves attention. Discriminating between stimuli requires attending relevant features of those stimuli. To the extent that those relevant features serve as reinforcers, the attending response may constitute an operant. Indeed, an  $S^D$  may (conditionally) reinforce an *observing* response that produces it (Shahan and Podlesnik 2008). This may be demonstrated in a modified mixed schedule with positive reinforcement and extinction components, in which a separate observing response turns the mixed schedule (lacking differential  $S^D$ ) into a multiple one (with differential  $S^D$ ).

Operant approaches to language provide a similar example. For instance, something akin to semantic categories appear to emerge from conditional discrimination (or *matching-to-sample*)

training. Two  $S^D$  that set the occasion for the same response (e.g., the written word “APPLE” and a picture of an apple set the occasion for saying “apple”) may acquire *functional equivalence*, wherein any of the trained stimuli (e.g., the written word, the picture, and the spoken word) may serve as  $S^D$  for responses related to the other stimuli (e.g., selecting the picture of an apple from other pictures). Equivalence relations between stimuli may underlie important functions related to language and cognition (Sidman 2009).

A broader approach to social behavior – including language and communication – is embodied in the notion of *verbal behavior*, or “behavior reinforced through the mediation of other persons” (Skinner 1957, p. 2). Verbal contingencies involve responses from one organism that serve as  $S^D$  or as outcome for the response of another organism. Asking for an apple is both a response that is reinforced with an apple, and an  $S^D$  indicating to someone else that giving an apple would be reinforced with a “thank you.”

The maintenance and propagation of social practices are likely to rely on the imitation of such practices as observed in others. *Observational learning* involves the change in behavior because of the consequences observed when others produce that behavior (Greer et al. 2006). Observing the successful courtship behavior of conspecifics, for instance, may increase the probability of engaging in similar courtship behaviors. Such *vicarious reinforcement* involves overlaying observing contingencies directed to the model on otherwise simpler operant contingencies operating on the model.

These examples illustrate a key advantage of an operant-conditioning approach to complex behavior: its modularity. Even the most complex environment-behavior interaction, when modeled as a schedule of reinforcement, may be grounded on simple and tractable components. From an operant perspective, the complexity of complex behavior lies in the interplay between these simple components.

### Behavioral Mechanisms

The concept of operant conditioning identifies potential efficient causes of change in simple and

complex behavior. This concept, however, does not specify the mechanisms that underlie such change. Such mechanisms may be physiological or behavioral. The former identifies the material (neural) substrate of operant conditioning in particular species; the latter identifies more general processes that take place during conditioning, which may be implemented in various substrates. This section provides a succinct overview of the behavioral mechanisms of reinforcement.

Drawing a simile with natural selection, Skinner (1981) suggested that operant conditioning selects among populations of responses (*repertoires*), favoring those that are reinforced and hindering those that are punished. Reinforcement may select responses through local, contiguity-based mechanisms, such as assignment-of-credit algorithms (Staddon and Zhang 1991). Alternatively, Premack (1965) proposed a more global mechanism, based on the constraints that contingencies of reinforcement impose on the repertoire. According to this latter view, if freely available, (unreinforced) operants such as lever pressing are less likely than activities supported by the reinforcer, such as eating. Contingencies of reinforcement, such as FR 5, make access to the most likely activity dependent on the less likely activity, such that eating 1 pellet/min can only occur if the organism emits at least 5 responses/min. According to *Premack's principle*, reinforcement of relatively unlikely operants occurs because they are required for more likely activities supported by the reinforcer. Contemporary behavioral economic views on reinforcement are an elaboration of Premack's early proposition. These views conceptualize all the possible allocations of time across activities as a multivariate utility function; contingency constraints shifts the arg max of this function; such shift constitutes operant conditioning (Rachlin and Burkhard 1978).

Whereas the response-reinforcer association may select a response from the organism's repertoire, the Pavlovian  $S^D$ -reinforcer association may confer incentive-motivational properties to the  $S^D$  that energize the selected response (Killeen 1994). The Pavlovian-instrumental transfer demonstrates the capacity of stimulus-reinforcer associations to energize reinforced behavior.

## Conclusion

Operant conditioning is one of very few psychological concepts from early twentieth century that has not only persisted in research practices, but has infused itself into and grown in importance in a broad range of fields, including animal cognition, behavioral pharmacology, special education, artificial intelligence, and behavioral economics. Its ostensible simplicity and heuristic power are at the same time alluring and misleading. Although prevalent in animal behavior, strict experimental control is necessary to demonstrate operant conditioning, as potential confounds with unconditioned and induced behavior are everpresent. Perhaps its capacity to explain human behavior is narrower than what Skinner (1953) envisioned, but there is no question of the omnipresent role of operant conditioning in human behavior – the tweets and chatter feed that keep humans coming back to their mobile devices confirms the original insights of Skinner.

Operant conditioning provides a framework to ground and operationalize otherwise ambiguous constructs, such as *contingency* and *value*. In doing so, it guides the search for the mechanisms underlying learning and reinforcement and highlights unresolved conceptual issues regarding the distinction between these mechanisms and the procedures to study them. Furthermore, empirical research on stimulus control, induced behavior, schedule control, conditioned reinforcement, choice behavior, and other related topics has informed theory and broadened our models of instrumental behavior. This is reflected in the metaphors such models have spawned: behavior as a reservoir that can be filled or depleted, as musculature that may be strengthened or weakened, as a force that may be opposed, as a limited resource to be allocated, as a state that may be dwelled in or transitioned through. Operant conditioning remains the most powerful framework to put purposeful behavior under experimental control and to unveil the mechanisms that govern it. New developments in operant conditioning are likely to find applicability in new fields, spawn more sophisticated models, and inspire more compelling metaphors.

## Operational Sex Ratio (OSR)

Yzar S. Wehbe and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

### Definition

The operational sex ratio (OSR) is the proportion of fecund females to sexually active males in a population at a given time.

### Preface

Note that this entry discusses neither the primary sex ratio (sex ratio at conception) nor the secondary sex ratio (sex ratio at birth). For more information on factors that influence the primary and secondary sex ratios – factors such as temperature, level of inbreeding, and intensity of parasite infection – see another entry in this encyclopedia entitled *Sex Ratio* (Szala and Shackelford 2019).

### Introduction

Evolutionary approaches to biology have asked how sex ratio affects animal cognition and behavior (Fisher 1930). Sexual selection – a “special case” of natural selection – promotes traits that increase an individual’s ability to attract and retain

mates. Intrasexual competition – when members of one sex compete intrasexually to achieve sexual access to mates – is an important explanatory factor in the cognition and behavior of sexually reproducing species (Darwin 1871).

Sex differences in parental investment co-occur with sex differences in *potential reproductive rates* (Trivers 1972). A reliable indicator of reproductive rate is the minimum investment that each sex must contribute to produce offspring (i.e., obligate parental investment). Specifically, the sex whose minimum investment in parenting is larger will have the lower potential reproductive rate. In most sexually reproducing species, females' higher obligate parental investment is grounds for their sexual choosiness and selectivity, prompting males to compete intrasexually for access to mates (Trivers 1972). Both sexual selection theory and parental investment theory generate predictions concerning the effects of biased sex ratios on animals' cognition and behavior.

Biased sex ratios are expected to intensify intrasexual competition among members of the abundant sex that perceive cues to mate scarcity (i.e., when potential mates are scarce relative to the number of same-sex rivals). The more abundant sex experiences greater competition for mates. The members of the scarcer sex benefit from improved mating opportunities (Fisher 1930), along with the luxury of increased choosiness in their selection of a mate (Emlen and Oring 1977). For members of the abundant sex, mating prospects are more restricted because of the greater number of same-sex rivals (Emlen and Oring 1977). A male-biased environment, for example, limits men's mate choices and can intensify some aspects of male–male competition (Pedersen 1991).

## Working Definitions

The adult sex ratio (also known as the tertiary sex ratio) is the ratio of adult males to adult females in a population. The OSR is the proportion of fecund females who are available to mate to sexually active males (Emlen and Oring 1977; Kvarnemo and Ahnesjö 1996). Different studies define OSR

in different ways. OSR is typically measured either as the ratio of males to females (Emlen and Oring 1977) or the ratio of males to (males + females) (Kvarnemo and Ahnesjö 1996). Using the former approach, an OSR of 1 is even, an OSR greater than 1 is male-biased, and an OSR below 1 is female-biased. Using the latter approach, an OSR of 0.5 is even, one higher than 0.5 is male-biased, and one lower than 0.5 is female-biased.

A third approach to measuring the OSR is “sex-neutral” and can be thought of as a ratio of competitors to potential mates or competitors to (potential mates + competitors); it is called the competitor-to-resource ratio (CRR). If the competitors to (potential mates + competitors) formula is used, then the CRR will equal 0 when the environment contains only opposite-sex others, the CRR will equal 1 when the environment contains only same-sex others, and the CRR will equal 0.5 when it is even. The CRR is a useful way to measure the OSR because it allows researchers to compare studies about male and female behaviors (Grant et al. 2000); CRR is equal to the OSR for males, and for females, the CRR equals  $(1 - \text{OSR})$ . This approach shares the benefits of log-transforming the ratio of competitors to potential mates (Weir et al. 2011) without the need for transformations.

In humans, the OSR is sometimes measured as the ratio of “marriage-age” men to “marriage-age” women in the local mating pool. Marriage age is typically considered to be between 15 and 49 years (Guttentag and Secord 1983).

## Is the OSR Usually Stable or Fluctuating?

A recent investigation of owl monkeys – a socially monogamous primate species – suggests that it may be erroneous to assume an equal OSR in monogamous species, as researchers have done in the past (Fernandez-Duque and Huck 2013). Rather, sexual selection models should assume unequal yet fluctuating OSRs, even in highly pair-bonded species, given the unmated “floaters” that may disrupt mating dynamics by affecting group composition. Many other factors have also been found to destabilize OSR. For example,

Del Giudice (2012) identified multiple factors that cause fluctuations in either OSR or adult sex ratio. These factors include the following processes. First, stochastic fluctuations in the adult sex ratio increase as the population size shrinks. These fluctuations are especially strong when populations have less than a few hundred individuals. Second, sex-specific mortality and geographic distribution destabilize the adult sex ratio via delayed feedback mechanisms. Third, if the mating age is different for each sex, OSR tends to fluctuate when populations shrink or expand. Fourth, OSR is destabilized when younger and older individuals compete over mates.

### Factors that Influence the Operational Sex Ratio

Many other factors may affect OSR, and these factors vary across species. They include the type of mating system, the stability of pair-bonds, and sex differences in potential reproductive rate (Clutton-Brock and Parker 1992; Del Giudice 2012). Factors that influence the potential rate of reproduction can indirectly affect the OSR. These factors may include contextual considerations such as food availability or nesting sites.

### The Cognitive and Behavioral Consequences of Changes in OSR

The ways in which OSR affects cognition and behavior vary across species. In some species, changes in OSR may even prompt sex role reversals (e.g., Fritzsche et al. 2016). A recent meta-analysis suggests that mate scarcity is related to increases in displays of mate-guarding, aggression, and courtship behavior (Weir et al. 2011). Another meta-analysis revealed that courtship competition and courtship propensity, but not courtship frequency, increased when fewer mates are available (de Jong et al. 2012).

Sex ratio theory predicts that intrasexual competition increases with mate scarcity (Emlen and Oring 1977; Kvarnemo and Ahnesjö 1996). For example, aggressive female-female competition

occurs at most OSRs, but in several fish species, females become the more competitive sex in highly female-biased OSRs (Forsgren et al. 2004). The influence of mate scarcity on intrasexual competition has been documented in naturalistic and experimental observations of many species including fishes (e.g., Forsgren et al. 2004), amphibians (e.g., Lee and Park 2009), birds (e.g., Colwell and Oring 1988), rodents (e.g., Bonatto et al. 2015), hyenas (e.g., Curren et al. 2015), and nonhuman primates (e.g., Mitani et al. 1996).

### OSR Studies in Humans

Compared to other mammals, human males invest exceptional effort in caring for offspring (Geary 2000; Buunk and Fisher 2009). Rates of female competition are higher in species that engage in pair-bonding and biparental care like our own, because monogamy and paternal investment beget mate choosiness among males (Fernandez-Duque and Huck 2013). Consequently, women must also compete intrasexually to secure and retain high-value mates (Clutton-Brock 2007).

Male-biased sex ratios are associated with lower average marital age among women; the authors explain that when women are scarce, they have more bargaining power and are able to find commitment at an earlier age (Kruger et al. 2010). Some seminal evolutionary predictions concerning the effects of biased sex ratios in humans came from Pedersen (1991): in male-biased sex ratios, men increase the number of offspring that they produce as well as increase resource provisioning, parenting activities, and violence toward both men and women. Indeed, studies suggest that preliterate societies find it more permissible for a husband to severely punish his adulterous wife when the society has a male-biased sex ratio (Guttentag and Secord 1983).

In humans as well as other animals, sex ratios influence a wide range of social behaviors. A review of evidence linking surplus men to more violence sheds light on the theoretical and empirical challenges that remain (Schacht et al. 2014). The authors caution that expecting a

relationship between competition over mates and violence is likely based on untested assumptions and might be masking interesting patterns.

Seemingly paradoxically, both female-biased and male-biased sex ratios can increase violence and crime. These discrepant findings may represent manifestations of different dynamics (Del Giudice 2012). For example, male-biased sex ratios increase male-male competition, but the competition may manifest in circuitous ways (e.g., by increasing competition for status or access to economic resources; Barber 2009). A longitudinal study of the effects of varying sex ratios in three English-speaking nations found that rates of violent crime were predicted by male-biased sex ratios (Barber 2003). Some of the violence in male-biased sex ratio environments may, however, be explained by the relative surplus of men, not by the ratio itself (Messner and Sampson 1991). In female-biased sex ratios, the percentage of men who marry at a younger age diminishes on account of men's increased short-term mating opportunities and decreased incentive for commitment (Kruger and Schlemmer 2009). Men's aggression and violent crime may simultaneously increase to attain these casual mating opportunities (Barber 2011). Several studies support this hypothesis, finding cross-sectional associations between female-biased sex ratios and higher proportions of violent crime (Barber 2009, 2011). At least in modern-day societies, female-biased sex ratios seem to increase male violence (Del Giudice 2012). Further research is needed to determine under which specific conditions female- and male-biased sex ratios increase aggression and toward whom.

Relatedly, cross-sectional research suggests that sexual choosiness is correlated with sex ratios, such that members of the scarcer sex express greater selectivity regarding the *qualities* they desire in a mate (e.g., Stone et al. 2007). The relationship between mate scarcity and decreased selectivity in the mating domain has also been the subject of experimental investigation. Using doctored sex ratio cues to alter perceptions of mate availability, Watkins et al. (2012) found that females expressed less choosiness when men were perceived as scarce versus abundant. The

researchers also found evidence of another mating rule: if the sex ratio is unfavorable (i.e., mate scarcity), people pay more attention to cues that index the mate value of potential sexual rivals. This mating rule presumably increases the individual's vigilance to mating rivals under conditions of intense competition.

Experimental studies have also found that sex ratio could have wider implications, such as changing how men make financial decisions (Griskevicius et al. 2012). In particular, increasing the perceived sex ratio to be more male-biased led males, but not females, to: (1) favor immediate over delayed monetary gains, (2) increase their motivation to borrow money, and (3) decrease their motivation to save money. This evidence suggests that young single men might respond to increased mate competition by expending additional effort to attract a romantic partner.

A recent theoretical paper examined the potential links between male mate-guarding behaviors, mate scarcity, and the evolution of human monogamy (Schacht and Bell 2016). The authors argue that the adaptive problem of mate scarcity may represent one of the key selection pressures that paved the way for human monogamy. If mate-guarding behaviors were successful in solving the problem of mate scarcity, then we should expect a range of such mate-guarding behaviors – not just intrasexual aggression – to be upregulated in response to cues to this adaptive problem.

## Conclusion

The sex ratio is widely believed to be a key ecological determinant of not only the availability of potential mates but also the *intensity* of competition for those mates, thus affecting many types of behaviors (see Weir et al. 2011). Sex ratio theory predicts that animals will intensify the tactics they use to secure a mate under conditions of mate scarcity. Correlational research surveying trends within populations has shown that OSR is related to human mating and parenting patterns (Del Giudice 2012). Many of these patterns can be understood as resulting from the trade-off between parental investment and mating effort.

Individuals of a given species are expected to have flexible, context-sensitive adaptations that enable them to respond to environmental and contextual fluctuations in an adaptive manner (Al-Shawaf et al. 2019). Sex ratio is one key contextual factor that reflects the degree of intrasexual competition and plays an important role in animal behavior and cognition. Given that sex ratio is a widespread aspect of the social lives of many sexually reproducing species, hypotheses and theories involving sex ratio can yield insights in many different species and domains (Del Giudice 2012).

## Opposable Thumb

Pierre Lemelin<sup>1</sup> and Daniel Schmitt<sup>2</sup>

<sup>1</sup>Division of Anatomy, Department of Surgery, Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada

<sup>2</sup>Department of Evolutionary Anthropology, Duke University, Durham, NC, USA

## Synonyms

Hand; Pollex; First digit; Prehensility; Grasping; Precision grip; Primates

## Definition

A complex term describing the anatomy and movements of the thumb of primates with specific meaning when applied to humans.

## What is an Opposable Thumb?

When asking a layperson to identify one feature that distinguishes humans from the rest of mammals, most people would likely move their first digit and say, “we have an opposable thumb.” In describing an opposable thumb (also known as the pollex), some people would stress how it sticks out on the side of the hand away from the other digits (a characteristic of most primates); others would emphasize the manner it contacts the index finger to form a pincer grip. Most people have been taught that the opposable thumb is a human character, though some would say it is found in nonhuman primates as well. The thumb of human beings is in fact capable of a very complex motion known as opposability, which allows the pulp or fleshy pad of the thumb to contact that of another digit, most often the index finger. This complex motion is promoted by a combination of bony, muscular, and touch reception and neural control features allowing the thumb to move in different planes and apply just the right amount of pressure, so that objects of different weight, shape, and texture can be sensed, held, and retained by a single hand (see Kivell et al. 2016 for in-depth reviews for each one of these topics). This ability to retain an object with one hand against the pull of gravity is what defines a hand capable of prehensility and typifies the hand of all primates (Napier 1961, 1993). Although prehensility can be achieved without opposition, a hand lacking prehensility cannot achieve opposition. In this way, the terms opposability and prehensility go hand in hand so to speak.

## Opposable Thumb: A Definition Based on Anatomy and Behavior

When examining and comparing the hands of different primates to each other and to

nonprimate mammals like tree shrews and rodents, key features can be easily identified: elongated fingers bearing flattened nails instead of claws and a long thumb diverging away from the other digits (Fig. 1). Historically, these features have been interpreted as adaptations for arboreal life and often used to classify the hand of primates as “opposable” (Haines 1958). In this context, the term opposable can be confusing. Anatomically, an opposable thumb can be defined as the first digit diverging away from the other digits. Behaviorally, an opposable thumb can refer to the ability of the pollex to converge toward the fingers using a motion known as opposability. Extensive variation exists within primates in these features, including thumb length and its degree of

divergence from other digits (Fig. 1) and the ability to achieve true opposition. Any attempt to define a thumb as “opposable” or capable of “opposability” requires careful consideration of both anatomical attributes and the behavior involved.

The broadest definition of opposability from both anatomical and behavioral perspectives involves a thumb diverging away or opposed relative to the other digits and the ability to assist the fingers in grasping an object securely with only one hand. However, a stricter and more precise definition of opposability more commonly used by human anatomists and clinicians focuses primarily on the thumb and its movements. Compared to most other primates, the human thumb is

**Opposable Thumb, Fig. 1** Hand diversity among primates and tree shrew. Compare the length and degree of divergence of thumb between different species. Hands not

to scale (Reproduced from Lemelin and Schmitt (2016) with permission from Springer Science + Business Media LLC)

proportionally longer relative to the fourth digit or ring finger (Almécija et al. 2015), and its palmar surface is rotated out of plane from that of the fingers when the hand is at rest. As such, the pulp of the thumb and fingers (particularly the index finger) can be approximated to grasp a small object. In order to achieve opposition with the fingers, the thumb has to move in three different planes simultaneously: abduction (thumb moves away from the palm), flexion (thumb curls toward the fingers), and medially rotate (thumb undergoes rotation along its long axis toward the little finger) (Fig. 2). This compound movement of abduction, flexion, and medial rotation that results into opposition is promoted by a joint at the base of the thumb that has a unique shape that resembles a saddle (Napier 1961; Fig. 2). A group of short muscles crossing that joint (known as the thenar muscles) are primarily responsible for movement of the thumb during opposition. It is worth noting that this joint morphology and musculature allows the human thumb to make pulp-to-pulp contact with any of the fingers, including the little finger (which, like the thumb, has its own set of short muscles known as the hypothenar muscles). In parallel with this anatomical arrangement, large areas of the motor and sensory cortices of the brain are devoted to movement of the thumb and other digits, as well as sensation over the skin of the palm, and specialized nerve endings responsible for light-touch discrimination populate the palmar skin with disproportionately high numbers for the thumb and index (see relevant chapters in Kivell et al. 2016).

Applying this definition of opposability to the thumb of other primates in general can prove difficult as it overlooks the diversity of hand behavior observed in many different species, some of which showing striking similarities with humans. A comparative approach is vital to determining which aspects of hand movement and thumb opposability are unique to humans and which aspects are common to all primates. In turn, this comparative approach is necessary to test theories that emphasize tool use and other manipulative behavior as the major selective pressure for the evolution of thumb opposability in humans.

Many nonhuman primates such as chimpanzees have short thumbs relative to the index finger (what is described as a low opposability index or ratio of thumb length over index finger length) compared to humans (Napier 1960, 1993). As such, objects are often picked up between the pulp of the thumb and the side of the index finger rather than its pulp surface as in humans (Napier 1960; Christel 1993). This is also true for other apes, with gibbons being extreme in that regard. Thus, true opposability as defined above appears to separate humans from apes (Napier 1960). Interestingly, human-like opposition can be observed in African Old World monkeys such as baboons, which are characterized by opposability indices closer to those of humans (Napier 1993). Baboons can certainly achieve pulp-to-pulp contact of the thumb and index finger, but appear far more limited in opposing the thumb with the little finger. In nonhuman primates known as strepsirrhines (a group of primates including the lemurs from Madagascar), tarsiers (small primates from Southeast Asia), and New World monkeys (monkeys from Central and South America or platyrrhines), the thumb appears to lack the ability to undergo medial rotation (Napier 1961). Therefore, Napier (1961) invoked the term “pseudo-opposability” to describe thumb movements in these nonhuman primates (Napier 1961, 1993). It should be noted that most primates described as having “pseudo-opposable” thumbs also lack the ability to move the thumb and other digits independently, making opposability as defined in baboons, apes, and humans virtually impossible (Bishop 1964).

Broad categorization (i.e., “opposable” vs. “pseudo-opposable”) tends to mask the natural variation in anatomy and behavior found in primates. For example, capuchin monkeys – New World monkeys with so-called pseudo-opposable thumbs – are capable of thumb opposition comparable to that of their African cousins. Like baboons that collect seeds and other small objects using thumb opposition, capuchin monkeys are also capable of very refined grips involving pulp-to-pulp movements of the thumb and index finger when foraging on palm nuts, often involving tools (see Chapter 12 in Kivell et al. 2016).

**Opposable Thumb, Fig. 2** Typical movements and joint morphology of the thumb of humans. (a) abduction of the thumb (thumb away from the palmar plane); (b) flexion of abducted thumb; (c) opposition of thumb with index finger;

(d) opposition of thumb with little finger; (e, f) saddle-shaped joint between the trapezium (short carpal bone) and thumb metacarpal (palmar view on *left*, side view on *right*). Scale bars are 2 cm

## Conclusions

The term opposable thumb is not easy to define as it has different meanings depending on the scientific field (see Napier 1960 and Lemelin and Schmitt 2016 for a discussion on the topic). For a zoologist, an opposable thumb describes its positioning relative to the other digits and its ability to assist the fingers in grasping securely an object with only one hand. This definition is broad and imprecise as it encompasses wide anatomical and behavioral variation. For a human anatomist or clinician, however, an opposable thumb applies to the ability of the pollex of humans to achieve a combination of movements (i.e., opposition) resulting in touching between its pulp surface with the pulp surface of adjacent fingers, mainly the index finger. This is a narrower and more precise definition. As such, the term opposable thumb should be used thoughtfully and properly, with its meaning carefully defined when used in any anatomical or behavioral study, or in any discussion for that matter, involving the primate hand.

## Introduction

When an animal moves, the image of its surrounding environment moves in the retinæ of the animal's eyes. The pattern of image motion (known as the “optic flow field,” OFF) bears rich information about the animal's own motion (termed “egomotion”), about the distance to various nearby objects, the speed of locomotion, the distance the animal has traveled, and several other parameters. This entry highlights some of the cues that are contained in the optic flow field and describes how they are used to control locomotion and enable safe and accurate navigation through the environment.

## The Relation of Optic Flow to Egomotion

When a flying animal turns (yaws) to the left, the image of the world appears to move to the right

and vice versa. The OFF generated by a leftward yaw (counterclockwise rotation about the dorso-ventral axis) is shown in Fig. 1a, where the individual vectors depict the direction and magnitude of the image motion at each location in the animal's visual field (which is assumed to be panoramic). The image motion (optic flow, OF) is directed horizontally everywhere. Its magnitude is zero in the dorsal and ventral regions of the visual field (the "poles") and maximum in the horizontal plane (the "equator") – the plane perpendicular to the axis of rotation. Figure 1b shows the OFF generated by a counterclockwise roll movement (a rotation about the antero-posterior axis). A counterclockwise roll causes the image to rotate clockwise about the roll axis and vice versa. Here again, the OF is largest in the plane perpendicular to the axis of rotation and is zero in the frontal and rear regions of the visual field. Figure 1c shows the OFF generated by an upward pitch movement (a rotation about the medio-lateral axis). Here the OF is largest in the plane

perpendicular to the pitch axis and is zero in both lateral regions of the visual field. Thus, yaw, roll, and pitch produce OFFs that have distinct "signatures"; and a rotation about any other axis would induce an OFF that is an appropriately weighted combination of these three canonical OFFs.

When an animal rotates, it experiences an OFF that is independent of the distances of the various objects in the environment – and this is true irrespective of whether the rotation is about the yaw, pitch, or roll axis or some other axis. However, the OFF that is generated when an animal *translates* (moves in a straight line) in any direction depends upon the distances of the objects in the environment, as well as their bearings. In general, during translation the magnitude of the optic flow generated by an object is proportional to the sine of the bearing angle of the object relative to the direction of translation and is inversely proportional to the object's range. Figure 1d shows the OFF generated by a forward translation in an environment in which all of the

**Optic Flow, Fig. 1** Optical flow fields generated by various motions of a flying animal. (a) Counterclockwise yaw; (b) counterclockwise roll; (c) upward pitch; (d) forward translation; (e) upward translation; and (f) rightward translation

objects are assumed to have the same range. The image motion is zero in the frontal and rear regions of the visual field and maximum in a plane perpendicular to the direction of translation. Figure 1e, f depict the OFFs generated by an upward translation and a rightward translation, respectively. Given these six characteristic optic flow fields, a flying animal could, at least in principle, estimate its instantaneous rotation in 3D by monitoring the responses of motion-sensitive neurons that are selectively responsive to each of the three “canonical” OFFs illustrated in Fig. 1a, b, and c. The responses of these three neurons would then encode the rates of yaw, roll, and pitch, respectively. Similarly, the three components of the animal’s translation would be encoded by the responses of three further neurons that are selectively tuned to the three OFFs shown in Fig. 1d, e, and f. Interestingly, electrophysiological investigations of the insect visual pathway have revealed large-field movement-sensitive neurons that display some of the characteristics illustrated in Fig. 1 (Krapp and Hengstenberg 1996), suggesting that these neurons may play an important role in the visual computation of an animal’s instantaneous egomotion in six degrees of freedom (three of rotation and three of translation). There is now ample evidence to indicate that at least some flying insects use the OFF to (a) infer their egomotion (rotation and translation) to stabilize their attitude and flight direction, (b) control the speed of their flight, and (c) estimate how far they have traveled by integrating, over time, the vectors representing the moment-to-moment translations and rotations that have occurred during the journey, through a process known as “Path Integration” (Srinivasan 2011a).

In what other ways could animals use optic flow information? Most insects are unable to rely on stereo vision to estimate the range to objects or surfaces, because the two eyes are not sufficiently far apart to acquire reliable stereo cues. Consequently, they need to rely heavily on optic flow information to measure the distances to objects and surfaces. When an insect flies past an object at a given speed, the closer the object, the larger the magnitude of the optic flow that it generates. Honeybees avoid collisions with obstacles by

moving away from objects that generate strong optic flow (Srinivasan 2011a). They negotiate narrow corridors by balancing the magnitudes of the optic flows that are generated by the two side walls, thus ensuring safe flight through the middle of the corridor (Srinivasan 2011b).

Honeybees regulate the speed of their flight by holding constant the total magnitude of the optic flow that they experience in the two eyes. Thus, they fly at a constant speed in a corridor of uniform width, but slow down as they fly through a progressively narrowing tunnel and speed up as they fly through a progressively widening tunnel (Srinivasan 2011b). This strategy ensures that the speed of flight is automatically tailored to the nature of the environment – a tightly cluttered environment enforces flight at a low, safe speed, whereas an open environment encourages a high flight speed. Honeybees orchestrate smooth landings on surfaces by holding constant the magnitude of the optic flow that they experience as they approach the surface. This ensures that the flight speed is automatically reduced as the bee approaches the surface, reaching a near-zero value at touchdown (Srinivasan 2011a; Baird et al. 2013). The beauty of this strategy is that it does not require continuous information about the distance to the surface or the speed at which the surface is approached.

Optic flow information can be used in a number of different ways to guide an animal’s behavior as it approaches a surface or as an object approaches it. For example, the projected time to contact the surface (TTC) at any instant of time is given by the ratio of the angular bearing of a visual feature on the surface, to the radial optic flow that the feature generates in the retina. When gannets plunge into the ocean to catch fish, they close their wings to streamline their entry into the water at a *fixed time* prior to contacting the surface, irrespective of the speed of the dive (Lee and Reddish 1980), suggesting that the nervous systems of these birds are indeed computing the TTC to determine when to close their wings. When pigeons are shown movies of a football approaching them on a collision trajectory, one class of visual neurons in the tectofugal pathway displays an abrupt increase in firing rate

approximately 1 s prior to the projected time to contact (Sun and Frost 1998). Interestingly, these neurons respond only if the object is on a direct collision course (when the OFF is purely divergent) and not when the trajectory is a “near miss” (when it includes a translational component). Another class of visual neurons in the thalamofugal pathway of the pigeon commences firing when a large approaching surface is ~6 cm from the eye, suggesting that these neurons are computing the *distance* of the approaching surface, rather than the time to contact. Interestingly, the heart rate of the birds also accelerates when the surface reaches this distance (Liu et al. 2008). These findings suggest that natural visual systems are capable of analyzing the pattern of optic flow in sophisticated ways, not only to infer their owners’ motion in the environment but also to compute the distance of an approaching object or the time to contact it, if a collision is imminent.

Survival requires natural organisms to deal and interact with other objects that are moving in the environment; these may be prey, predators, or a potential mate. Animals are very adept at detecting moving objects, even when they themselves are in motion. This is a challenging task, because the visual system of a moving animal experiences not only the object’s motion, but also that of the environment. A moving object cannot be reliably distinguished on the basis of motion parallax (the motion of its image relative to that of the background), because even a stationary object can generate motion parallax when it is nearer than the background. One way to detect a moving object reliably would be to compare the direction of motion of the image of the object with that of its immediate background. If these directions are different, the object is in motion. While it remains to be seen whether natural visual systems indeed adopt such a strategy, it has been applied successfully in machine vision systems (Strydom et al. 2016).

Once a moving object has been detected, it may be necessary to pursue it, or avoid a collision with it, or flee from it – depending upon the context. In flying insects, the control of pursuit is based on measurement of the angular bearing of the target and the optic flow that it induces in the

eyes of the pursuer (Land and Collett 1974). Various pursuit strategies have been documented, ranging from (i) simple pursuit, where the pursuer continually reorients itself to move directly toward the target; (ii) predictive pursuit – a more efficient strategy, where the pursuer effectively predicts the point of interception of the target and moves directly toward that point; and (c) motion-camouflaged pursuit, where the pursuer conceals its motion by moving toward the target in such a way as to produce precisely the optic flow that would be induced by a stationary object (Srinivasan 2011b). Imminent collisions can be avoided by steering away from objects that generate purely divergent flow on the retina. Furthermore, in a close encounter with a moving object, the optic flow generated by the object can be used to predict the minimum separation and the time at which this minimum separation will occur (Gunasinghe et al. 2016).

Space does not permit detailed description of the above strategies. However, many of them rely critically upon the analysis of optic flow. How is optic flow actually computed by the nervous system? While movement-detecting neurons in the visual pathway have been characterized and modeled for some time (Borst and Helmstaedter 2015), they do not seem to provide a veridical estimate of the OF, because their responses depend not only upon the speed of the image in the retina but also upon its contrast and its visual structure (Srinivasan et al. 1999). Tackling this conundrum is a continuing theme of current research.

Another theme of research that is receiving increased interest is the application of the principles derived from understanding how animals use optic flow, to the design of vision-based guidance systems for aircraft (Srinivasan et al. 2013). Biologically inspired systems are being developed for flight stabilization, automated collision avoidance, speed control, landing, visual odometry, and navigation. Like an insect or a bird, these systems are completely self-reliant – they use purely vision-based information and do not require complex external infrastructure such as GPS (Franceschini 2014; Strydom et al. 2016; Gunasinghe et al. 2016).

## Optimal Foraging Theory

Sarah Ritvo  
York University, Toronto, ON, Canada

Optimal foraging theory (OFT) predicts and evaluates how an organism behaves in response to problems encountered in its environment while searching for food (Commons et al. 1988). Motivated by a growing understanding of natural selection (Williams 1966), and the importance of energy in ecological systems, OFT was first introduced in the 1960s by two publications by MacArthur and Pianka (1966) and Emlen (1966). These seminal papers suggested that organisms' prey choices were selected for by evolution and guided by a tendency to maximize energy as a function of time spent feeding (Kamil et al. 1987). (Selection in biology is a natural process that results in the survival and reproduction of some organisms and not others with the result that inherited traits of the survivors are passed down to offspring, thereby

perpetuating those traits (“Selection,” 2017). The publication of Stephen and Krebs’ book *Foraging Theory* in 1986 further fortified and popularized the theory, inspiring many more publications on the topic that same year (Stephens et al. 2007). The most basic premise of OFT concerns efficiency and optimization: The organism that obtains food at the maximum possible rate will have a selective advantage over less efficient foragers of its species (Kurland and Beckerman 1985). Moreover, although acquiring food provides an organism with energy, it also *costs* time and energy to find, secure, and consume. Therefore, an organism that can minimize the time and energy required to acquire the maximum amount of energy from food increases its biological fitness (an organism’s relative capacity to survive and transmit its genes to offspring (“Fitness,” 2017). Also, referred to as Darwinian fitness). Consequently, according to the theory of natural selection, a species’ most efficient foraging pattern will be selected for (i.e., propagated).

To put this in perspective, let’s imagine that a species’ food source becomes limited. The members of this species that obtain food at the maximum possible rate, proportionate to their size, age, strength, and other physiological capacities (i.e., the optimal forager), will be better nourished than less efficient foragers of its species (Kurland and Beckerman 1985). Likewise, if an organism’s species faces other threats, whatever they may be, the optimal forager will have more time, energy, and strength to use in overcoming challenges associated with those threats. Even without any particular threat, an optimal forager will have more resources to dedicate to mating, parenting, and defending its offspring. In every one of these cases, the optimal forager will be more likely to survive and reproduce, thereby contributing to its species’ gene pool. OFT predicts then that (a) organisms will strive to acquire energy from food at the maximal possible rate and (b) optimal foraging behavior patterns will be perpetuated by being passed down from parents to offspring.

Optimal foraging is considered a multi-dimensional problem made up of several independent components including search, identification, handling, consumption, and utilization (i.e.,

digestion) (Commons et al. 1988). As an organism forages, environmental variations and other limitations affect each of these components in different ways (Commons et al. 1988). Consequently, the foraging process has been studied by isolating and manipulating each one of these components to analyze how various “constraints” (i.e., environmental variations and other challenges) affect them (Commons et al. 1988).

## OFT Model Components

Theoretical models are used to test hypotheses (i.e., possible explanations of phenomena). Models are formulated based on a hypothetical explanation of an observed phenomenon, idea, or process and then tested to see how accurate they are. That is, models enable predictions that can be compared with observable data. A successful model is one that can account for the relationships observed between factors of interest. Optimality and foraging models tend to share three common components: decision assumptions, currency assumptions, and constraint assumptions (Stephens and Krebs 1986).

### Decision Assumptions

Optimality models concern the “best” way to make a choice, whether that choice is made by the organism or by natural selection (e.g., What type of teeth should a shark have? What pattern should honey bees use to pollinate?). In optimality and foraging models, the forager’s “decision” that has been selected for analysis is often defined by translating that decision into one or more algebraic variables (e.g., speed, size, length, time, etc.). While decisions analyzed in “static models” are not dependent on time, and therefore can be represented by non-sequential lists of choices, dynamic models, on the other hand, involve decisions that depend on the timing of those choices. Because one choice in a dynamic model (e.g., honey bee pollinating path) can affect the organism’s future condition (e.g., amount of honey in the hive), which in turn can affect forthcoming decisions (e.g., number of larvae produced), dynamic models describe the optimal “path”

(i.e., sequence) of decisions. The decisions investigated by most OFT models focus on food exploitation: which food items to eat and when to leave a foraging area and move onto another (Stephens and Krebs 1986). Each of these questions is comprised of multiple decision variables that can be represented in different ways. For example, if we consider the latter problem, when to leave a foraging area, the decision variable is often “quantity of time spent in the foraging area” (e.g., the amount of time spent grazing a patch of grass). However, other decision variables could include the quantity or type of food ingested while foraging in that area.

### Currency Assumptions

A model’s currency is the variable that is optimized by the organism. In other words, it is the organism’s foraging “goal” or “payoff” (Hughes 1993; Stephens et al. 2007; Stephens and Krebs 1986). All OFT currencies concern long-term average energy rate maximization (i.e., how to acquire the most energy on average, over the long term, given the time and energy used to do so). The simplest OFT currencies can be defined as a food item’s value, less the cost of acquiring the food item (Stephens and Krebs 1986). For example, a popular currency used in OFT models is “energy intake per unit time spent foraging” (Shettleworth 1989). Once the decision variables and currency have been defined, the relationship between them must also be defined. For example, an investigator may analyze the relationship between the energy intake per time spent foraging (the currency) and the size of a food patch (the decision variable).

### Constraint Assumptions

A model’s constraints are variables that affect the relationship between the currency and the decision variable(s) (Stephens and Krebs 1986), that is, environmental, physiological, and informational factors that limit the forager’s available choices and the payoff obtained from those choices (Hughes 1993; Stephens et al. 2007; Stephens and Krebs 1986). Conventional OFT models assume three major constraints: (a) exclusivity of search and exploitation,

(b) sequential Poisson encounters, and (c) complete information. The first assumed constraint is straightforward; a forager cannot be two places at one time. That is, an organism cannot exploit prey or food patches while at the same time searching for food (Stephens and Krebs 1986). The second constraint concerns the timing of sequential foraging events; food items are encountered one at a time, and the probability of each food item in a short time period is constant (Stephens and Krebs 1986). The third constraint concerns the organism’s understanding of the rules of the model. OFT models assume that the forager knows or, at the least, behaves as if it knows the rules of the model, such as information about the foraging environment (Stephens and Krebs 1986).

### Conventional Models of Optimal Foraging Theory

Although, since its conception OFT models have advanced, expanded, and diverged, the most basic optimal foraging hypotheses stem from separating the act of foraging into “search” time and “handling” time and have been popular topics of study (Commons et al. 1988; Kurland and Beckerman 1985). “Search” includes behaviors dedicated to finding food, whereas “handling” refers to behaviors dedicated to obtaining and consuming food after it is found (e.g., pursuit, subduing, preparation, ingestion, etc.) (Kurland and Beckerman 1985). The two most influential examples include the prey and patch models (in foraging models, “prey” is conceived of as any distinct food item that a forager acquires (e.g., a mouse, a worm, a seed, grass, etc.)). Both are average-rate maximizing models, both focus on searching and encountering food, and both use Holling’s (1959) disc equation to calculate the average rate of energy intake (Stephens and Krebs 1986). However, they differ in that they analyze different decisions. The prey model analyzes the choice to *eat or continue searching* when a *food item* is encountered, and the patch model analyzes the choice of *how long* to forage when a *food patch* is encountered.

### The Prey Model

The prey model, also known as contingency theory, predicts what a forager will do when it encounters food in its environment. Will the forager stop and eat the food or continue searching for a more profitable food? To answer this question, each type of food is assigned an average handling time and an average value. The value of a food type is most often defined as its rate of energy intake (i.e., calories); however, other definitions, such as protein content, have also been used (Kurland and Beckerman 1985; Nakagawa 2009). For example, in herbivores, nutrient balance, digestion, inhibition, toxicity, and gut capacity have also been identified as important factors. Therefore, valuable herbivore food types are those that maximize intake of energy and nutrients while minimizing intake of digestion inhibitors and toxins (Freeland and Janzen 1974; Nakagawa 2009; H. R. Pulliam 1975; Westoby 1974). Nevertheless, for any organism, the “prey profitability ranking” or the “net yield” of a food type is defined as the ratio of its value to its handling time (Kurland and Beckerman 1985) (also referred to as “net payoff” and “net benefit”). When these factors as well as the net yield are known, an optimal foraging rule can be specified: A forager should stop searching for food and invest handling time for a food item only if, on average, it cannot maximize its food intake rate by passing up this food item to continue foraging and come across a more valuable food item (i.e., something better to eat). That is, a forager should only stop to eat when it finds a food item that has a small enough handling time, and a large enough caloric yield, that the forager is unlikely to do better by ignoring the food item to search for something better.

The results of the prey model make several predictions. The first as discussed above is *Ranking by Prey Profitability*: Food types are ranked based on the ratio of energy intake to handling time. The second is the *The Zero-One Rule*: Food item types are either always eaten when they are encountered or never eaten when encountered. If a forager encounters a high-ranking food item, and passes it up in search of another food item, the best possible scenario is that it will encounter *another*

high-ranking food. Therefore, there is no benefit to passing up a high-ranking food item; it should always be eaten. In comparison, when a low-ranking food item is encountered, and the opportunity loss due to consuming this food item outweighs the potential energy gain, then it never pays to eat a low-ranking food item. (Foraging opportunity loss is assessed by comparing potential gains from consuming a food item with the potential loss of the chance to consume a better food item.) In this way, The prey model predicts that it is always better to skip low-ranked food types in search of higher-ranked types, given how much time and energy it takes to consume them and their low caloric payoff. The last and most surprising prediction of the prey model is *Independence of Inclusion from Encounter Rate*: Whether a food type is included in an organism’s optimal diet is dependent only on the abundance of better food choices and not on that food’s own abundance (i.e., “encounter rate” or the likelihood a forager will come across a food type in its environment). That is, even if a low-ranked food item is abundant in a food patch, it should still be ignored. This prediction makes more sense when we consider that this model *only* asks *what* food should be eaten or ignored *within a homogenous* food patch. If a forager moves to a new patch, the model should be independently applied to the new patch scenario (Stephens and Krebs 1986). In this way, the prey model does not preclude the scenario in which an optimal forager might forage in a patch with unusually abundant low-ranking food items, if this abundance compensates for the low- value of the food.

### The Patch Model

Similar to food type selection, optimal foraging theory rules are also applicable to optimal “patch residence time” (Stephens and Krebs 1986), that is, predicting how long an organism will forage within a “patch” of food, among the patches available to them so as to maximize time and energy (Kurland and Beckerman 1985; Nakagawa 2009; R. H. Pulliam 1974; Pyke et al. 1977; Schoener 1971; Stephens and Krebs 1986). A patch is an area of an organism’s environment with a particular density and distribution of food. It differs

from the rest of the organism's environment based on food density; the patch is more, or less, dense with food than the surrounding environment. Originally proposed by Charnov (1976) as the marginal value theorem, the patch model hypothesizes that because most food patches contain limited resources, foraging a food patch will deplete it (Stephens and Krebs 1986) (also referred to as the patch choice theory). Consequently after a forager first enters a patch, it will experience diminishing returns, as the rate of energy intake decreases with time. Consequently, an organism should leave a patch it is foraging in when the average rate of energy intake in the patch (i.e., the calories available to be consumed) diminishes to match the average energy intake rate in the surrounding environment including the time it will take to search for and/or travel to a new patch (Nakagawa 2009; Stephens and Krebs 1986). In other words, although an animal can continue to increase its *total* caloric intake by foraging in a depleted patch, its time and energy could be more wisely used, by finding a new patch in which its rate of energy intake would be higher. It follows then that the patch model predicts that foragers will stay in (a) food patches with higher food density and/or higher value food longer than those that are less dense or contain lower-valued food types and (b) one food patch longer when surrounding food patches are scarce or far apart (Nakagawa 2009).

## Criticisms and New Concepts

Since the publication of Stephens' and Krebs' (1986) book and the flurry of publications inspired thereafter, OFT has become a focus of criticism and debate (Gould and Lewontin 1979; Pierce and Ollason 1987, so much so that by the mid-1980s, foraging scientists were hesitant to identify with OFT (Stephens et al. 2007). One of the most basic criticisms of this theory is that for the most part, OFT predicts inflexible and uncompromising behavioral responses. However, research indicates that animals are more likely to exhibit more gradual and incomplete responses, demonstrated via partial diet preferences and

variable patch residence times (Pyke 1984). Another popular area of debate surrounds how "optimality" is, or can be, defined (Stephens et al. 2007). Critics argue that natural selection is not sophisticated enough and does not have enough time to "perfect" traits. Moreover, many evolved traits may actually result as by-products of other traits that were selected for (Stephens et al. 2007). Ecologists in the field also questioned how applicable such simple OFT models are to the complex reality of natural environments.

Partly in response to these criticisms, new OFT hypotheses have developed. Stephens et al. (2007) identify some of the biggest conceptual advances to include (a) the recognition that foragers must weigh the trade-offs of compromised safety when foraging for food; (b) conceptual advances in "state dependence", the idea that a forager's choices may be influenced by state variables, such as level of hunger or fat reserves; and (c) consideration of the effects of group foraging and social foraging games between predator and prey, which takes into account the prey's behavior in addition to the predator's and proposes that the predator considers the consequences of its behavior and its prey's (Stephens et al. 2007).

## Optimal Group Size

Jeannine Holmes<sup>1</sup> and Suzanne MacDonald<sup>2</sup>

<sup>1</sup>York University, Toronto, ON, Canada

<sup>2</sup>Department of Psychology, York University, Toronto, ON, USA

Many animal species form groups for a portion or the entirety of their lives. Individuals benefit from forming groups when the advantages of aggregating – including foraging and hunting benefits, improved predator avoidance, increased conspecific threat avoidance (against infanticide and intergroup contests), cooperative infant care, and information sharing – outweigh the costs of group living – predominantly intragroup resource competition for food and reproductive opportunities, as well as increased exposure to disease.

Group size impacts access to food and the ability to respond to threats and has important fitness consequences (lifetime reproductive success). *Optimal group size* is the group size at which individual member fitness is maximized. Group size is influenced by ecological factors, namely food competition and risk of predation, which put pressure on the upper and lower limits of group membership until an intermediate, optimal size is reached. Intergroup competition is one such ecological constraint that favors larger groups as larger groups are better able to defend territory and food patches from other rival groups (the “resource defense model” (Wrangham 1980)). Even in situations where food patches or territories cannot be defended or when such

defense does not provide a net benefit, large groups may still be preferred over smaller groups to reduce the risk of predation, as larger groups are better able to detect predators and discourage attacks (Van Schaik 1983). Unfortunately, there are also costs associated with large group sizes. As group size increases, intragroup competition increases as limited food resources must be divided among more and more individuals (exploitation competition) and contests among group members over the limited food supply can prevent access to resources for some members (interference competition). Intragroup competition should thus favor smaller groups. It is this tension between intragroup competition, which encourages smaller groups, and intergroup competition and/or predation risk, which supports larger groups, that encourages group size toward an optimal, intermediate size.

A number of other ecological factors may directly or indirectly influence optimal group size. Seasonal food availability can impact optimal group size due to its effect on intergroup and intragroup competition. Generally, during times of food abundance optimal group size should increase. However, during times of food scarcity, optimal group size should decrease if food shortages cause increases in intragroup competition but increase if food scarcity causes increases in intergroup competition. The size, density, and distribution of food patches also impact group size (Chapman and Chapman 2000). Larger groups spend less time at a given patch as they deplete the patch more quickly and must move to the next patch sooner than smaller groups. When the density of patches is high, travel costs between food sources within a patch are low and thus larger groups should be supported. When large or small food patches are clumped together, travel costs are low between patches and larger group sizes can be supported (at least in the short term) as long as the clump of patches can support the group overall. When the distribution of patches is uniform, the density of the patches is expected to determine group size regardless of patch size, with higher densities supporting larger groups as travel costs are low and with lower densities supporting

smaller groups when patches are rare, as smaller groups can feed on one patch for longer periods. Threats of infanticide from rival conspecifics should encourage an increase in optimal group size as larger groups can better discourage and defend against attacks. Within a given group, optimal group size may differ for individuals of different ranks in the group's social hierarchy. Subordinate individuals are often responsible for group protection and thus generally benefit from larger groups that spread the costs of defense among a larger pool. Conversely, dominant individuals typically benefit from somewhat smaller groups that continue to provide efficient protection via subordinate members but have lower costs of intragroup competition.

Optimal group size will differ across species, populations, and even individuals within a given group due to the varying impact of the factors that affect the costs and benefits of group living. Understanding each group's optimal size will be important for conservation efforts both in terms of the expected survival of current species and populations as climate change and human encroachment force animals into areas that may not allow for optimal groupings and also in terms of the success of reintroduction efforts and captive breeding programs.

## Definition

The numerical position of an object.

What knowledge do we acquire when learning a list of items? Ladd and Woodworth (1911) proposed that we encode ordinality, stating that “Associations are certainly formed, not only between successive members of a list, but also between individual members and their positions in the series” (p. 578). In contrast, Ebbinghaus (1913) argued that while associations were formed between adjacent items, associations were not formed between items and positions but “...beyond intervening members to every member... The strength of the threads varies with the distance of the members” (p. 94).

To test his hypothesis, Ebbinghaus (1913) developed the derived list paradigm. Ebbinghaus (1913) learnt six 16-syllable lists to the point where he could repeat each list without error. He then used the items in each list to construct derived lists of 1, 2, 3, or 7 degrees of remoteness. For example, if the original series was  $A \rightarrow B \rightarrow$

$C \rightarrow D \rightarrow E \rightarrow F \rightarrow G \rightarrow H \dots \rightarrow P$ , then a list of 1 degree of remoteness would look like  $A \rightarrow C \rightarrow E \rightarrow G \rightarrow I \rightarrow K \rightarrow M \rightarrow O$ , etc., and a list of 3 degrees of remoteness would look like  $A \rightarrow E \rightarrow I \rightarrow M \rightarrow B \rightarrow F \rightarrow J \rightarrow N$ , etc. Ebbinghaus (1913) reported that the speed with which a list was learnt was a decreasing function of the degree of remoteness. That is, derived lists with 1 degree of remoteness were learned faster than those with 2 degrees of remoteness, lists with 2 degrees of remoteness were learnt faster than those with three, and lists with 3 degrees of remoteness were learnt faster than those with seven. Importantly, all of the derived lists were learnt faster than a control list in which items from the original series were randomly arranged. Ebbinghaus (1913) used these data to conclude that remote associations play a key role in serial learning.

A potential problem with the Ebbinghaus (1913) method, however, was the control condition that he used. His control lists were composed of 16 items, taken from 6 lists he had previously learnt, and placed in a random order. In light of Ladd and Woodworth’s (1911) ordinal position hypothesis, a list constructed in this manner would lead to negative, rather than neutral, transfer. This is due to the fact that mixing the order of items for the control list creates interference between the old item-position associations and the new item-position associations that must be formed. To address this issue, Hakes et al. (1964) replicated Ebbinghaus’ (1913) derived list experiment with the exception that the control list was composed of novel items. On the derived lists, Hakes et al. (1964) reported no significant difference in the number of trials required to reach one perfect recitation for participants learning a derived list of 1, 2, or 3 degrees of remoteness and those learning the control list and concluded that “The present results are in accord with those of other recent experiments (serial to paired-associate transfer) in providing no support for the associative theory of serial learning” (p. 513).

Interestingly, a variation of Ebbinghaus’ (1913) method of deriving a list has provided the strongest evidence in support of the ordinal position hypothesis. Ebenholtz (1963) trained two

groups of subjects on a 10-item list composed of nonsense syllables ( $A \rightarrow B \rightarrow C \rightarrow D \rightarrow E \rightarrow F \rightarrow G \rightarrow H \rightarrow I \rightarrow J$ ). Once the participants acquired the list, Group 1 was trained on a derived list in which the even or odd items from the first list maintained their ordinal position (e.g., even items:  $X1 \rightarrow B \rightarrow X2 \rightarrow D \rightarrow X3 \rightarrow F \rightarrow X4 \rightarrow H \rightarrow X5 \rightarrow J$ ), while Group 2 was trained on a derived list in which the ordinal position of the even or odd items from the first list was changed (e.g., odd items:  $F \rightarrow X1 \rightarrow H \rightarrow X2 \rightarrow J \rightarrow X3 \rightarrow B \rightarrow X4 \rightarrow D \rightarrow X5$ ). Each X represents a novel list item. Ebenholtz (1963) found that participants in the maintained group learned the positions of the familiar list items significantly faster than participants in either the changed group or a control group. This finding suggests that participants encoded the ordinal positions of the list items during serial learning and used that information to guide responding on the derived lists.

In nonhuman animals, studies have typically employed variations of the simultaneous chaining paradigm to investigate ordinality (Chen et al. 1997; D'Amato and Colombo 1989; Harris et al. 2007; Orlov et al. 2000; Scarf and Colombo 2011; Terrace et al. 1995). For example, D'Amato and Colombo (1989) trained monkeys on a 3-, 4- and 5-item list and, once subjects were performing above 75% correct in a single session, inserted "wild cards" on approximately half of a subject's daily trials. The "wild card" was a novel stimulus that was substituted for an existing list item. For example, on a 5-item list, a subject may be presented with the items A, W, C, D, and E, with W representing the wild card item. On this trial, the wild card has replaced the second item of a 5-item list, and in order to correctly complete the trial, the subject must respond to the wild card at the second position (i.e.,  $A \rightarrow W \rightarrow C \rightarrow D \rightarrow E$ ). The wild card was placed equally often in each ordinal position on the 3-, 4-, and 5-item lists. On the 3-item list, there were three types of wild card trials (e.g.,  $W \rightarrow B \rightarrow C$ ), on the 4-item list, there were four (e.g.,  $A \rightarrow W \rightarrow C \rightarrow D$ ), and, finally, on the 5-item list, there were five (e.g.,  $A \rightarrow B \rightarrow W \rightarrow D \rightarrow E$ ).

The performance of monkeys and pigeons on the 3-, 4-, and 5-item lists is shown in Fig. 1. The

monkeys performed above chance on the three 3-item, four 4-item, and five 5-item wild card lists. Although the performance of pigeons trained on the 3-item lists was comparable to monkeys, pigeons trained on the 4- or 5-item lists performed at chance, with the exception of performance on the 4-item  $A \rightarrow B \rightarrow C \rightarrow W$  and 5-item  $A \rightarrow B \rightarrow C \rightarrow D \rightarrow W$  lists. The performance on these wild card lists, in which the wild card replaces the end item, can be explained by the subject simply responding to the baseline items first (e.g.,  $A \rightarrow B \rightarrow C \rightarrow D$ ) and then responding to the wild card item (W) by default. The high performance by pigeons on the  $W \rightarrow B \rightarrow C$  and  $A \rightarrow W \rightarrow C$  lists is also easily accounted for without invoking knowledge of ordinal position.

The inability of Terrace et al.'s (1995) pigeons to place the wild card items correctly on the 4- or 5-item lists would suggest that they do not acquire knowledge of each item's ordinal position. However, the performance of Terrace et al.'s (1995) pigeons may also be attributed to a contextual variable. Indeed, when learning a 4- or 5-item list, it is common for pigeons to take 2000–2500 and 3000–3500 trials, respectively, to reach a 75% criterion. Given this extensive training, it is possible that when a novel item is substituted for an interior item, pigeons may have a strong tendency to first respond to within-list items before responding to the novel list item. Indeed, on the series  $A \rightarrow B \rightarrow C \rightarrow W$  and  $A \rightarrow B \rightarrow C \rightarrow D \rightarrow W$ , which represent 25 and 20% of total wild card trials, respectively, the subject is reinforced for responding to within-list items before responding to the novel item. Lists in which the wild card replaces the last item are also those on which the 3-, 4-, and 5-item groups perform at a comparable level. A similar within-list tendency has been found with human subjects (Stromer and Mackay 1993). This tendency would result in the same errors Terrace et al. (1995) suggest reflect an inability to position the wild card at the correct ordinal position. In summary, the wild card task may not be the best procedure with which to evaluate ordinal knowledge in pigeons.

To address this issue, Scarf and Colombo (2011) trained three pigeons on three 4-item

**Ordinality, Fig. 1** The performance of monkeys and pigeons on the 3- (top panel), 4- (middle panel), and 5-item (lower panel) wild card trials. The dashed line represents chance level of performance

lists (List 1, A1→B1→C1→D1; List 2, A2→B2→C2→D2; and List 3: A3→B3→C3→D3) and then presented them with maintained (e.g., A1→B2→C3→D1) or changed (e.g., A1→C2→B3→D1) lists. Scarf and Colombo’s (2011) pigeons not only performed significantly better on the maintained lists than the changed lists but also performed significantly above chance on their very first session on the maintained lists. These data suggest that similar to monkeys, pigeons also understand ordinality.

Unified definition of human orgasm is difficult: in spite of the intuitive individual recognition of the phenomenon, the research on orgasm has not converged on a broadly accepted definition. Rather, the definitions range from those focusing on the subjective sensation to the release of neural tension, or the bodily changes involved, such as muscular contractions (Mah and Binik 2001). This multitude of descriptions reveals the multifaceted, individually variable and thus highly subjective experience of human orgasm. For the purposes of this short description, we will delineate the orgasm here as a neuroendocrine event, alluding to the two main physiological signaling systems involved, i.e., the nervous and the hormonal, serving as the starting point. We will first focus on external description of male and female arousal and orgasm and its neurological and hormonal underpinnings, followed by its possible roles in the evolution. Finally we will briefly address some of the historical interpretations.

## Physiology of Human Orgasm

In both males and females, orgasm is preceded by the arousal stage, characterized by a rush of blood

into genitalia and triggered either by cognitive or tactile stimulation. In males, the rush of blood into penile corpus cavernosum, enabled by the relaxation of smooth muscles lining the blood vessel walls (see below), leads to penile erection. What is commonly addressed as ejaculation consists of two parts – the emission, during which the seminal fluid is collected in the prostatic part of the urethra, and the ejaculation from the penis. We equal here ejaculation with male orgasm, even though the field is not in complete agreement on this topic (Alexander et al. 1993). The fact that pathological disorders can affect each of these processes separately suggests that their regulation is at least to some extent distinct. Arousal, emission, and ejaculation are a complex coordinated interplay of several smooth muscles of the ducts connecting testes with urethra (epididymis and vas deferens), of the seminal vesicle, prostate, and several sphincters, which likely contribute to the pressure with which semen exits at ejaculation. Ejaculation also includes the involuntary action of striated pelvic muscle, anal sphincter, and perineal muscles. The trigger of ejaculation is likely not simply a matter of the degree of arousal; however, the actual mechanism is not understood so far. In females, the arousal and orgasm has traditionally been described in four stages: excitement, plateau, orgasm, and resolution (Masters et al. 1966). Plateau is the stage in which, similar to male arousal, blood flow into the genitalia is increased, leading to vaginal lubrication and vaginal dilation, as well as clitoral swelling. Clitoris is the female anatomical counterpart of penis and consists of external visible parts (glans and labia) and an appreciable internal portion (paired bulbs and crura with erectile corpora cavernosa; O'Connell et al. 2005; Puppo and Puppo 2015). Female orgasm similarly manifests itself as involuntary rhythmic muscle contractions of pelvis, uterus, and vagina as well as lower anus. As in males, also in females, it is not understood what underlies the transition from arousal to orgasm.

Some of the neurobiological mechanisms coordinating the above phenomena are known (reviewed in Komisaruk et al. 2006). Cranial and spinal nerves integrating parts of autonomous

(involuntary) and somatic nervous systems innervate genitalia. Most generally, it is thought that both parts of autonomous neural system are involved in control of sexual activity: the parasympathetic slow-acting system in arousal and the sympathetic quick-acting system in orgasm. The parasympathetic innervation of genitalia stems from cranial vagus (Komisaruk et al. 2004) and the sacral pelvic neural fibers, the later associated with pudendal spinal nerve (but see recent suggestion that the pelvic fibers may in fact be part of the sympathetic system; Espinosa-Medina et al. 2016). The established sympathetic innervation stems from the hypogastric plexus of lower abdomen, associated with lower lumbar spinal nerves. Neuroimaging studies of the brain during stimulation have shown activation of several brain regions. The somatosensory innervation of genitalia in both sexes maps to parts of medial cortex (Komisaruk et al. 2011), whereas the human orgasm itself has been shown to activate numerous additional brain regions. Mapping female and male orgasm (ejaculation) showed activity in the hypothalamic nuclei, cerebellum, preoptic area, bed nucleus of stria terminalis, amygdala, hippocampus, lower brainstem, and frontal cortex (Whipple and Komisaruk 2006; Georgiadis et al. 2007; Komisaruk and Whipple 2008; Komisaruk et al. 2011; Huynh et al. 2013). Thus at least to a great extent, male and female orgasm-associated brain circuits overlap. Interestingly, many of the same circuits have been also associated with male ejaculation in rodents indicating parts of homologous process across animal species (Baum and Everitt 1992) although there are also differences when compared to primates (Michael et al. 1999).

What we know about the neurotransmitters involved in signaling during arousal and orgasm is derived mainly from targeting of specific neurotransmitters to treat nervous conditions in other disease contexts, such as depression. Several drug classes have been shown to affect arousal and/or orgasm in humans. These include drugs that act directly on transmitter receptors, such as agonists of serotonin receptors or antagonists of inhibitory noradrenalin receptors, both of which enhance aspects of sexual behavior. Further, the use of drugs that inhibit degradation of transmitter in

the synapse, or inhibit its reuptake (e.g., SSRI), has indicated that serotonin and dopamine modifications significantly modulate sexual reaction and orgasm (Montejo-Gonzalez et al. 1997; Balon 2006; Higgins et al. 2010).

In addition to neural circuits in other brain regions, orgasmic activation of the hypothalamus also triggers a hormonal response of the pituitary. The pituitary is an endocrine gland, which functionally connects two signaling systems, the neural and the hormonal system. Its function is triggered by the neural signal to the brain, conveyed to pituitary either by direct neural connections (posterior pituitary) or by the signals secreted from the neurons to the hypothalamic vessel plexus, and transferred into pituitary by the blood (anterior pituitary). Orgasm triggers a surge of pituitary hormone secretion in humans, which is particularly pronounced in females (Exton et al. 1999, 2001). The strongest hormonal surge is that of prolactin; however, also a minor surge of oxytocin has been reported (Carmichael et al. 1987). The physiological significance of these surges is unknown. Because the long-term elevation of prolactin inhibits libido, the prolactin surge has been suggested to inhibit the promiscuous behavior in females (Kruger et al. 2002) after coitus. However, the fact that women (in contrast to men) lack refractory period after orgasm suggests that this explanation of the brief prolactin surge is unlikely (Bianchi-Demicheli and Ortigue 2007). An alternative suggestion is that the PRL peak is a remnant of evolutionarily older process that induces ovulation and therefore has had a reproductive function in the evolutionary past (see below). Indeed, prolactin peak is associated with normal ovulation in women (Vekemans et al. 1977; Braund et al. 1984). This will be discussed further in the section on evolution of orgasm. Mechanistically, the prolactin peak is likely a consequence of brief interruption of dopamine signaling in the hypothalamus, where dopamine constitutively inhibits prolactin secretion; thus, dopamine inhibition (e.g., due to transient increase in serotonin signaling) can account for the prolactin surge (Bianchi-Demicheli and Ortigue 2007). The existence of orgasm-associated surge of the second pituitary hormone,

oxytocin, has been variably reported (Kruger et al. 2003) and is likely rather due to projections of the separate neuronal signals from genitals and breast to the same brain region in hypothalamus (Cross and Wakerley 1977). The reproductive functional significance of oxytocin is likely found in causing the contraction of the myoepithelial cells in breast milk glands as well as in the reproductive tract, involved in milk ejection in the breast, and propagation of the egg cell (and, in labor, the fetus) through the reproductive tract. The social function that is often attributed to oxytocin is that of enhancing partner bonding, in analogy to what is observed in rodents (Carter 1992; Witt et al. 1992; Cho et al. 1999; Razzoli et al. 2003). However, the putative orgasm-associated surge reported for humans is not only variably detected, but very small (~1.3-fold change in female orgasm; Carmichael et al. 1987) compared to the experimental dosages in rodents (up to tenfold change in experimental settings showing effect on social behavior in rats; Witt et al. 1992). Given that oxytocin is suggested to reinforce future trust and sexual behavior also in humans, it is not clear whether orgasm (sex) contributes to this effect or whether it rather stems from other aspects of intimacy or relationship.

## Types of Female Orgasm

Whereas males perceive orgasm relatively uniformly, women report different types of orgasm associated with stimulation of different parts of genitalia (“vaginal,” “cervical,” vs. “clitoral” orgasm, Grafenberg spot). The innervation of genitalia mentioned above includes separate branches supplying parts of genitalia, and these all likely respond to stimulation. There is, in addition to spinal nerves, evidence for innervation independent of the spinal cord, which has been suggested to account for cervical orgasm (Sansone et al. 2002; Komisaruk and Sansone 2003; Komisaruk et al. 2004). Moreover, it is important to realize that the clitoris is an organ much larger than glans clitoris that is externally visible and extends internally dorsolateral, parallel to the urethra and also to the ventral vaginal wall (O’Connell et al. 2005;

Puppo and Puppo 2015). It is thus likely that vaginal penetration can achieve indirect stimulation of internal clitoral parts, leading to perception of the ventral vaginal side as “G-spot,” so-called after German physician Graefenberg (1950), who studied the role of urethra in female orgasm.

## Evolutionary Origin of Orgasm

To identify the evolutionary origin of any trait requires recognizing the corresponding trait in different species and then identifying the last common ancestor of the lineages in which the trait is present. Finding a corresponding trait of human orgasm is difficult, in part because research on orgasm has been primarily conducted in humans and primates, and therefore orgasm has been very narrowly characterized to capture human-specific characteristics, difficult to detect in other animals (Pfaus et al. 2016). For this reason, little is known about the presence, or the role, of corresponding traits across mammals. It is very unlikely that the physiological basis of orgasm has arisen only in human or primate lineage. However, it is likely that the trait has acquired human-specific modifications in human lineage.

It is useful here to focus separately on male and female orgasm for a moment. The orgasm in males is associated with ejaculation and sperm transfer and therefore crucial for reproduction. Prompt ejaculation of relatively large amount of sperm thus is generally assumed to be a sufficient explanation for the existence of orgasm-like impulse in species with internal fertilization. Indeed, erection and ejaculation are widely spread across animal kingdom, in particular in amniotes, that is, the reptiles and mammals.

In contrast to male orgasm, the human female orgasm is not required for reproduction, and in fact a high percentage of women do not experience orgasm during reproductive (penetrative) sex (Hite 1976; Lloyd 2005). To nevertheless explain its existence, various reproductive roles were suggested, by which the presence of female orgasm would still positively affect the number of offspring; ranging from mate choice (Alcock 1980; Puts et al. 2012), to bonding, to

enhancement of sperm transfer (Levin 2011a), to name a few. So far no evidence could be found for such effects of orgasm on reproductive fitness (Levin 2011b; Zietsch and Santtila 2013). However, whether the female orgasm presently has a (reproductive) function or not reveals little definitive about why it originated, as the function of a trait often changes during the trait’s evolution. An important critical review of existing theories of origination and maintenance, specifically of female orgasm, was published in 2005 by Elizabeth Lloyd (2005). Lloyd pointed out the difference between sexes in how closely reproductive sex is related to orgasm: whereas reproductive sex is effective in achieving orgasm in men, it is highly ineffective in women. This makes the explanations based on direct reproductive effect implausible. Lloyd systematically evaluated 21 theories based on the evidence their authors provided and rejected all but the *by-product* hypothesis (Symons 1979). This hypothesis states that the female orgasm is a side effect of male orgasm, meaning that it originated and is maintained (in spite of having no function), because the male counterpart is required for reproduction. To understand why female trait would be so dependent on male trait, it is useful to remember that the female clitoris is homologous to the male penis and therefore shares the very similar genetic basis. As this basis is passed sometimes to male and other times to female progeny, it becomes partially modified in the developmental context of particular sex to build either clitoris or penis. Whereas the adult morphology in males and females is different, not all the features of male and female physiology can be genetically decoupled, and physiology of orgasm could be one such feature. The necessity of orgasm in males is thus suggested to drive the origin and maintenance of the female orgasm.

In 2016, Pavlicev and Wagner proposed a new hypothesis for female orgasm (Pavlicev and Wagner 2016). The authors provided evidence that female orgasm may be a remnant of the neuroendocrine signal, which induces ovulation in some species. Ovarian cycles are spontaneous in women, meaning ovulation does not depend on environmental signals or the pheromones or

copulatory stimulation by a male, releasing a single egg cell periodically every ~28 days (ovulation). However, in many mammals, ovulation is not spontaneous but rather dependent on an external trigger, which is often tactile genital stimulation during copulation. These species are called induced ovulators and include many carnivores (cats, ferrets, etc.), camels, rabbits, etc. Pavlicev and Wagner suggested that the orgasmic neuroendocrine signal that triggers pituitary hormones in human female orgasm still carries a signature of the signal that triggers ovulation (via pituitary) in induced ovulators. Moreover, induced ovulation is phylogenetically older and thus may have been a predecessor of spontaneous ovulation. Many traits lose functions during evolution, but traces still stay around. Additional evidence is seen in female genital morphology: coincident with evolution of spontaneous ovulation, also the position of strongly orgasm-triggering glans clitoris has changed. In species, which require induction by copulation, the clitoris is positioned within copulatory canal where it gets directly stimulated, whereas in the species that ovulate spontaneously, the clitoris is removed from the copulatory canal. The latter at the same time may explain the rarity of female orgasm during reproductive (i.e., penetrative) sex.

## Historical Cornerstones of Research on Human Orgasm

The irregularity of female orgasm in particular has intrigued thinkers since the ancient times. Aristotle already has reflected on the question whether or not female orgasm is important for reproduction (reported in Leroi 2014). Early on, the female sexuality, including the lack of orgasm, has been strongly associated with psychological state, and the sexual massages were used as treatment for hysteria, *hysteria* standing for a very general description of female mental and behavioral disorders (psychosexual connotation is still reflected in *hysterectomy* for uterine removal). Particularly influential in this context up to the present day were the writings of Sigmund Freud, the Viennese founder of psychoanalysis. Freud in his work on

mental disorders laid great emphasis on the experiences during early development, as well as specifically on sexuality. With respect to female orgasm, he proposed a natural developmental succession from infantile clitoral to mature vaginal orgasm (Freud 1905). The grave consequence of this influential conceptualization was that the absence of vaginal orgasm during reproductive sex has become interpreted as a signature of mental immaturity, of women stuck in a childlike sexual state—quite overlooking that this is rather the norm than a deviation. One of the early remarkable woman sexologists was Marie Bonaparte (Bonaparte 1933). Herself a psychoanalyst, she opposed Freud's concept, proposing that glans clitoris remains the main source of mature female orgasm and that the lack of orgasm during reproductive sex is due to the lack of clitoral stimulation during penetrative sex, deriving from displacement of clitoris from the vagina, typical of human anatomy. In 1930s she collected over 200 individual measurements of the distance between vagina and clitoris and found a correlation between that distance and a decreased rate of copulatory orgasm (a dataset more recently re-evaluated by Wallen and Lloyd 2011). Best known empirical research on human sexuality and orgasm from the twentieth century is undoubtedly that by the zoologist Alfred Kinsey from Indiana University (Kinsey et al. 1948, 1953), followed by the rich work of William Masters and Virginia Johnson, at Washington University in St. Louis (Masters and Johnson 1960; Masters et al. 1966, 1974, 1993; Kolodny et al. 1979). An important contribution in particular in female sexuality came from Shere Hite. In a comprehensive review of female sexual experience, she first documented the high percentage of women that rarely or never experience orgasm in penetrative sex—thus considered dysfunctional in Freud's theory—however are perfectly able to do so in masturbation (Hite 1976). From the 1970s to 1990s, evolutionary theories of female orgasm were discussed by a wide variety of authors from the ethologist Desmond Morris (1967) to the behavioral biologist John Alcock (1980), to the paleontologist Steven J. Gould (1991). With the exception of the work of Symons, Gould, and

Lloyd, all attempts to explain the evolution of orgasm, discussed above, have been adaptationist, meaning that they attempt to explain the origin of female orgasm by its assumed current utility in humans (Wagner and Pavlicev 2016). This debate was synthesized in the influential book by Elisabeth Lloyd (2005). Finally, major contributions to the current knowledge of the physiology of female orgasm were made starting in the 1990s by Barry Komisaruk and collaborators.

## Definition

*On the Origin of Species, The Origin of Species, or On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* is a book published in 1859 by English naturalist, biologist, and geologist Charles Darwin.

## Introduction

*On the Origin of Species* is a scientific book considered to be the first structured introduction to modern evolutionary biology. It popularized the process of evolution by natural selection. Much of the data inspiring and supporting Darwin's theory was collected during his voyages to the coast of South America (including Galápagos), Australia, and South Africa

(Desmond and Moore 1991). At the point of publishing the book, support for evolutionary ideas was already growing in the field of biology both in academic and public settings, and an evolutionary framework was used to explain novel biological findings. However, due to the close relationship the English academia had with the conservative Church of England, nontheological explanations were perceived as controversial because they claimed that humans are not unique or superior to other living organisms, and, therefore, it took several dozen years for the ideas described by Darwin to be widely accepted in academia.

One of the reasons for the popularity of *On the Origin of Species* was the fact that, despite describing complicated biological processes, it targeted readers who were not professional biologists. The book was written in a way that was both scientifically insightful and also relatively easy to read. Darwin was familiar with the scientific literature of the time, and he was able to compose the book in an engaging style. Darwin was a known scientist, and his ideas were used as strong supportive evidence of scientific naturalism by biologist and anatomist Thomas Henry Huxley, who promoted secularization of science. Approval of Darwin's and Huxley's ideas was not immediate; it took some decades before the theory of evolution by natural selection was accepted and approved by the majority of academia. The acceptance of evolution by natural selection as a unifying concept for all the life sciences was sealed around the middle of the twentieth century by the emergence of the extended evolutionary synthesis, which highlights the importance of two unifying concepts of an evolutionary approach to biology – reciprocal causation and constructive development.

## History of Evolutionary Thought

Before the presentation of Darwin's ideas, the main framework for understanding life was natural theology, which was based on a literal interpretation of the Bible according to which all species were perceived as God-made in their final form. Even Carl Linnaeus's taxonomy

considered species to be in their ultimate form. That understanding of life stood in opposition to a view favoring progressive, gradual development of species from their ancestral forms. The idea of transformism (transmutation of species) was popularized at the end of the eighteenth century by Erasmus Darwin, a grandfather of Charles Darwin, and then, at the beginning of the nineteenth century, further developed by Jean-Baptiste Lamarck. Lamarck introduced the process later called Lamarckism and explained that organisms are progressively transforming towards greater complexity. However, at that point, English scientists were still often Church of England clergymen, and, therefore, the abovementioned processes were construed as designed and executed by God (Bowler 2003).

Charles Darwin was exposed to Lamarckism from the early years of his childhood. He attended a school run by a preacher and then, in 1818, joined the Anglican Shrewsbury School (Desmond and Moore 1991). In 1825 he went to the Edinburgh University and studied medicine. In 1826, he abandoned his medical studies and, for 4 months, assisted Robert Grant's empirical research on marine invertebrates (Browne 1995). Then, he went to Cambridge University. Under the supervision of the botanist John Henslow, Darwin started studying science in a natural theology framework, and with the geologist Adam Sedgwick, he pursued the ideas of catastrophist geology, which understood transformation as a process of adapting to repeated worldwide catastrophes, such as the biblical flood (Bowler 2003; Browne 1995). An important event in Darwin's life was the expedition aboard the *Beagle* that he joined as a geologist and naturalist at the end of 1831. Reading the *Principles of Geology* by Charles Lyell and discovering fossils of *Glyptodon* (then considered extinct gigantic armadillos), Darwin understood that there is no gap between animals and humans and started to suspect that species might not be "fixed" and "final" (Bowler 2003; Keynes 2000; Larson 2004).

After returning to England, Darwin further analyzed empirical data from both living animals and fossils of extinct species and, by drawing conceptual evolutionary trees, started to drop

Lamarck's ideas about independent species transforming into their advanced forms and formed an idea about species evolving from a common ancestor. After seeing an orangutan, he acknowledged its similarity to humans (Desmond and Moore 1991). After comparing methods of professional breeders with the natural processes of specialization he observed, he became aware of the similarities between these phenomena. Then, while continuing his work, exchanging letters, and corresponding with scientists such as Joseph Hooker and Herbert Spencer, he began to write down and soon published his findings. By 1856, his theory of evolution by natural selection was almost fully formed.

Another English biologist, naturalist, anthropologist, geographer, and explorer, Alfred Russel Wallace, came to similar conclusions as Darwin and in 1855, published a paper with a theory that all species developed from closely related species (Wallace 1855). However, Darwin decided not to discuss his findings with Wallace and instead decided to work on his own project instead and in 1856 began formulating the first draft of a book (Quammen 2006). During the process of writing a book, Wallace sent Darwin a draft of his description of a process similar to the one described by Darwin; the difference was mainly due to Darwin perceiving the newly discovered process as similar to the one used by breeders and focused on competition, whereas Wallace placed emphasis on ecological pressures and described processes similar to the process nowadays called group selection. By arrangement of Darwin's friends and colleagues, and in order to preserve Darwin's precedent, a paper co-authored by Darwin and Wallace was read at a London scientific meeting, titled *On the Tendency of Species to form Varieties; and on the Perpetuation of Varieties and Species by Natural Means of Selection* (Bowler 2003; Darwin & Wallace 1858; Larson 2004; Quammen 2006). Neither Darwin nor Wallace was present, and this first public presentation of evolution by natural selection did not generate much interest or discussion.

In 1859, Darwin reached out to ask John Murray whether he would be interested in publishing his book, which he planned to title

*An Abstract of an Essay on the Origin of Species and Varieties Through Natural Selection*. Murray agreed, but after some discussions, they decided to modify the title; Darwin hoped the new title would include *Through Natural Selection or the preservation of Favoured Races* (Desmond and Moore 1991). An early draft of the book was entitled *On the Mutability of Species*. The title kept changing; the next version was *An Essay on the Origin of Species and Varieties*, then *An Essay on the Origin of Species*, and finally, with Murray's encouragement, the title became *On the Origin of Species*, with the subtitle *by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life*. The book with the final title was published on the 24th of November 1859. The book sold out quickly, so a second edition with corrections was soon published. Twelve years after the *On the Origin of Species* was published, George Mivart published a book called *On the Genesis of Species* in which he contested Darwin's ideas. The sixth edition of *Origin* – and the last one published during Darwin's lifetime – included an additional chapter addressing Mivart's opinions. In addition, in the sixth edition, the term "evolution" was used for the first time, and the title was changed to the simpler *The Origin of Species* (Darwin 1859). The book was published in several other countries, but some translations were inaccurate, often because the translators subverted the content of the book to support their own beliefs. That happened, for example, with the first German translation. While Darwin was still alive, his book was translated to German, Swedish, Danish, Polish, Hungarian, Spanish, and Serbian (Freeman 1977).

## Content of the Book

The main revolutionary message described in *On the Origin of Species* was that, in contrast to what was previously believed and accepted by learned peoples and the public, species did not appear as separate from each other and in their final, God-given form. Instead, they were changing from previous forms because of the process of *natural*

*selection*. Darwin first explained evolution by comparing it to artificial selection in animals and plants and then provided evidence from various disciplines that evolution is indeed happening (Darwin 1859).

The content of *On the Origin of Species* differs slightly depending on the edition of the book. The title page and introduction consist of quotes by several prominent thinkers. Darwin also mentions Wallace and highlights that he came to the same conclusions as the one presented in the book. In the third edition and beyond, Darwin provided a brief history of the development of the idea of evolution. In the book, Darwin explains the idea of variation under nature and domestication. He describes the process of breeding plants and animals, both in modern times and in the past, and introduces the idea of selective breeding, using the example of pigeons. Then he further clarifies how vague the distinction between varieties and species is and highlights how much variability there is in nature. He explains his concept of *natural selection*, or *the survival of the fittest*, and how a feature that is profitable will tend to be preserved and passed to offspring and therefore will become more frequent in the population. He draws the analogy with selective breeding that it sharpens the feature that is preferred by a breeder. He proposes the idea of competition-driven sexual selection to explain features that are sexually dimorphic. He highlights the complexity of adaptations and provides the first draft of an evolution-based taxonomy in a form of a "tree." He provides details about his ideas of heredity and variation, but at the point of writing the book, the field of genetics was not yet developed, and, therefore, Darwin did not understand how heritability works. Darwin also explained the idea of common descent and how, in sexually reproducing species, offspring express features of both their father and mother (Darwin 1859).

Darwin addresses possible problems with the theory, including that there often is no evidence for the existence of forms between two species. He did, however, present examples with

intermediate structures, e.g., flying lemurs or flying squirrels, explaining that they may share features of transitional forms of other flying mammals, such as bats. He also observed the unique behavior of honeybees constructing hexagonal cells, implying they must have evolved from bees making round cells, but the behavior of building hexagonal cells evolved to conserve space for honey. He also observed that hybrids of two different species occasionally are fertile, challenging the natural theological claim that hybrids are infertile by God's design (Darwin 1859).

In later editions of the book, Darwin added another section in which he addresses criticisms. Critics argued that some adaptations could not have appeared because of natural selection because they do not seem to have any adaptive purpose. Darwin replied that some features might either be by-products of the evolution of other features or adaptations we do not yet understand.

Darwin includes chapters addressing the geological record. He points out that many forms of fossils seem to appear suddenly. However, he argues fossils are relatively rare, and therefore the available fossils do not accurately reflect the past variability of species. Darwin was sure that, as geology progressed, more data would be collected and analyses that are more detailed would become possible. He also anticipated that changes happen at different paces, depending on how quickly the environment changes. Some species evolve more quickly, and some remain the same for a longer time. In the final sections of the book, he writes about geographic distribution of plants and animals. He points out that, despite environmental similarities between various geographical locations, fauna and flora differ between locations, e.g., in warm regions of Australia, Africa, and South America. He realized that migration barriers were important to explain the distribution of species on different sides of these barriers (e.g., mountains). He explains his thoughts about taxonomy and the way species are classified. Finally, in the last section, he reviews previous assumptions and highlights that he anticipates that evolution by natural selection will revolutionize biology (Darwin 1859).

## Reception of *On the Origin of Species*

Due to the fact that the book did not only have revolutionary biological, anatomical, and morphological assumptions, but also indirect implications standing in opposition to religion, it caused vigorous debates. There was massive resistance against the idea of evolution by natural selection. Some scientists, such as Joseph Hooker, Asa Gray, Thomas Huxley, Ernst Haeckel, and Henry Bates, supported the idea, but the resistance of some biologists was caused by the fact that they did not understand the idea, e.g., despite Darwin's arguments, they still believed that evolution is progressive and purposeful. Resistance among other readers was associated with the fact that accepting Darwin's idea might lead to social reformation; also, it was often the case that understanding of Darwinian ideas was superficial. There were many scientists in the field of biology that did not agree with Darwin's ideas, e.g., Richard Owen, British anatomist, perceived the gradual changes as a process that was caused by God or George Campbell, the Duke of Argyll, who argued that specific features of animals were designed by a Creator. Despite the fact that Darwin did not explicitly mention that humans also shared ancestry with all other species (and he did not do so until 1871 when he published his book, *The Descent of Man, and Selection in Relation to Sex*), heavy hints were dropped, and the idea could have been indirectly concluded from the rest of the text. The first widely popularized attempt to place humans on the phylogenetic tree belonged to Huxley, who, in 1858, noted similarities between the anatomy of apes and humans. Outside of England, evolutionary ideas faced similar challenges. As time progressed, more and more scientists were convinced and accepted evolution by natural selection as the explanation for all life (Bowler 2003).

Even the scientists that agreed with Darwin's ideas were sometimes skeptical or dubious about some of the processes he described. Carl Nägeli raised a concern that features that do not provide any adaptive benefit could not be retained by natural selection. Mivart agreed with Darwin that such features could have been linked with features

that were adaptive but then later criticized natural selection and supported the idea of “directed” evolution; his arguments were addressed by Darwin in later editions of *On the Origin of Species* (Bowler 2003; Mivart 1871).

Another wave of criticism came from readers alerted that the idea of evolution by natural selection supported secularism. Although Darwin did not explicitly discuss the origin of humans, the content of the book indirectly placed humans among animals, which was not in line with accepted dogma of religion. Evolution and recent findings in geology regarding the age of the Earth posed a direct threat to the standard biblical creationist view. Even those agreeing with Darwin often assumed natural selection is a mechanism directed by the Creator. To placate these critics, in the second edition of the book, Darwin added the phrase “by the Creator” to the sentence “Life, with its several powers, having been originally breathed [by the Creator] into a few forms or into one. . .” Despite taking that step, the book’s content deviated from established thinking of the time, and its implications irrevocably shifted the bounds of popular conversations, causing debates about issues regarding the origin of humans, the human soul, and spirituality, in general, that in some forms continue to this day (Bowler 2003; Larson 2004).

## Conclusion

*On the Origin of Species* authored by Charles Darwin argues that all species evolve by the natural selection of inherited, small variations increasing the individual’s ability to survive, compete, and reproduce. The data from Darwin’s notebooks, including the very early ones, suggests he perceived evolution as a process that links biological findings together, making it possible to understand life, and included humans in biological model of flora and fauna. In the conclusion of his book, he highlighted that evolution will be a foundation for other sciences, such as psychology and natural history. He was right; *On the Origin of Species* is widely considered the most innovative contribution to modern science, and Darwin himself is considered one of the most influential

individuals in the history of science. The book is centrally important in pursuing both scientific and humanist ideas.

## Ornamentation

Sandra Winters

New York University, New York, NY, USA

### Definition

A trait used to attract the opposite sex during mate choice.

### Introduction

Many animals exhibit conspicuous characteristics such as brightly colored body regions or exaggerated physical structures. When these traits function during mate choice to increase the likelihood of their bearer attracting a mate, they are referred to as ornaments. The quintessential example of an ornament is the peacock's tail: consisting of bright colors and patterns, and enlarged far beyond the relatively small tails of peahens, peacocks' tails are presented to females during mating displays. Peahens then accept or reject a male based in part on his tail characteristics (Petrie et al. 1991). Ornaments are often sexually dimorphic, with one sex ornamented and the other not, but mutual ornamentation is also observed (Andersson 1994).

Ornamentation is linked to reproductive success, with individuals that display more elaborate ornaments enjoying a selective advantage. Ornamentations are therefore defined not based on appearance but on function, and conspicuous traits are only considered ornaments when they have been shown to influence mate choice. The term ornamentation has generally been used to refer to visual characteristics such as colorful or elaborated body regions, and some authors explicitly define ornamentation as a morphological trait. However, other types of ornaments have also been reported, such as those that involve smell, vocalizations, or electric pulses, and ornaments can also be multi-modal (e.g., both visual and acoustic). This entry therefore defines ornaments as any traits that are used to attract the opposite sex during mate choice.

## Sexual Selection Dynamics

The extraordinary appearance of conspicuous traits such as the peacock's tail puzzled early biologists because such traits would seemingly make their bearer more vulnerable to predators. To explain the evolution of these ostentatious characteristics, Charles Darwin (1871) developed the theory of sexual selection, which posits that such traits can evolve when they increase individuals' reproductive success. Darwin separated sexually selected traits into two categories based on their function: armaments – such as large antlers or canines – facilitate competition with same-sex individuals for access to mating opportunities (via ► [Intersexual Selection](#), this volume), and ornaments aid in attracting mates of the opposite sex (via ► [Intersexual Selection](#), this volume). Ornamentation therefore results from a competitive regime in which mating decisions are influenced by characteristics of the opposite sex. Individuals with more impressive characteristics will be chosen more often and will therefore enjoy higher reproductive success, leading to an exaggeration of these traits over evolutionary time. Thus, the peacock's tail becomes more elaborate over time because this is linked to higher fitness. While ornaments by definition result from mate choice, it is important to note that intrasexual competition and intersexual mate choice can both support and oppose one another; therefore, a trait can be influenced by both selective processes simultaneously.

Many species are sexually dimorphic, with differential expression of traits like degree of ornamentation between sexes (Andersson 1994). Sexual selection acts on both sexes; however, the strength of selection is dependent upon which sex is the limiting resource in reproduction (see ► [“Parental Investment”](#), this volume). In many animals, females invest more in offspring and therefore tend to also be choosier in selecting mates. This generates a competitive regime in which males often compete for access to females and are therefore subject to stronger intersexual selection for attractiveness to potential mates. This results in males that are more ornamented relative to females. In ► [sex role reversed species](#)

(this volume) in which females tend to compete for access to males, this trend reverses and females are the more ornamented sex (Andersson 1994). This tendency for differential ornamentation is relative, however, and research is increasingly showing that there is scope for male choosiness and female ornamentation across species (Clutton-Brock 2007).

## Selective Advantages and the Evolution of Ornaments

Why are ornaments attractive to members of the opposite sex? The selective advantage and evolution of ornamentation has been a hotly debated and researched topic in evolutionary biology since Darwin's time, and several hypotheses have been presented on the topic (reviewed by Andersson and Simmons 2006).

Some hypotheses are based on nonadaptive mate choice and posit that the expression of ornaments is not linked to any adaptive trait in the individuals expressing them. Rather, they are meaningful only in a mating context. For instance, the sensory bias hypothesis (Ryan 1998) suggests that ornaments evolve because they exploit sensory-response systems in other behavioral domains, such as foraging. A species that forages on red fruit, for example, may have evolved a preference for red, and a red ornament could "piggy back" on this preference. Another commonly cited hypothesis is ► [runaway selection](#) (this volume), which predicts that ornaments evolve when an originally adaptive trait and a related mating preference are exaggerated via a self-reinforcing positive feedback loop. The mating preference (often considered to arise from a sensory bias) is initially selected for because it leads to offspring that tend to have more adaptive trait values. The runaway process then takes over, with the ornament and the mating preference both increasing proportionally, and often becoming genetically linked such that they are inherited together. Because each yields a mating benefit (i.e., attracting mates via the ornament or producing offspring with ornaments that are attractive to mates), both remain under positive selection. In

this way, the ornament becomes far more exaggerated than would be adaptive in a nonmating context. At some point, the costs of the ornament match any mating benefits, and the trait and preference stabilize. Runaway selection models are difficult to test empirically, but remain good candidates for the evolution of particularly elaborate ornaments.

Other hypotheses for the evolution of ornamentation focus on mate choice associated with adaptive traits. Closely tied to research involving signal honesty, these hypotheses focus on ornaments as signals of individual quality, with more elaborate ornaments indicating a higher quality mate. The underlying quality that is signaled can be of varying types. For instance, more elaborate ornaments may be associated with mates that provide direct benefits to the chooser, such as access to a high quality territory or absence of transmissible disease. Alternatively, the good genes hypothesis (this volume) suggests that ornaments evolve because they are associated with advantageous characteristics that are heritable (i.e., indirect benefits), such as good foraging skills or a strong immune system. The good genes hypothesis has been of particular interest to biologists because many species lack bi-parental investment, and therefore genetic contributions to offspring are often the only adaptive explanations for ornamentation. However, this hypothesis is theoretically problematic because mate choice based on a heritable trait should reduce associated genetic variability across generations (i.e., because many individuals are choosing the same mates), which would in turn lead to reduced selection on mating preferences. This contradiction is known as the lek paradox (Kirkpatrick and Ryan 1991). Many solutions to the lek paradox have been proposed, which mostly involve identifying mechanisms that can maintain variability in the face of mate choice and positive selection. These include solutions based on environmental change, mutation rates, and parasite co-evolution. A popular model is the genetic capture model (Rowe and Houle 1996), which suggests that ornaments linked to individual condition are influenced by many genetic loci, and this large target for selection helps to maintain variability.

Alternatively, trade-offs between selective pressures may maintain trait variability, such as opposing selective pressure from natural and sexual selection, or when a trait is beneficial for one sex but detrimental to the other. New work analyzing the genetic underpinnings of ornaments has helped to further clarify the ways in which trait variability can be maintained in the face of mating preferences (e.g., Johnston et al. 2013).

It is important to note that many proposed hypotheses for the evolution of ornamentation are not mutually exclusive. Different explanations are often supported by different biological systems, and given the diversity of ornaments observed in nature, it seems likely that they have evolved via a variety of mechanisms across the animal kingdom.

## Signal Honesty and the Costs of Ornamentation

A major question associated with adaptive explanations for ornament evolution is that of signal honesty (► [“Honest Signaling”](#), this volume). Many ornaments are condition dependent, with the strength of the ornament associated with individual quality, such that the ornament can be used as a proxy for individual characteristics (Andersson 1994). So what prevents cheaters from engaging in false advertising? In some cases, a signal is directly linked to some physical characteristic that cannot be faked; such signals are referred to as indices. For example, the tones of some acoustic calls are inherently linked to body size. Not all signals follow this pattern, however, so other explanations must be sought. Much of the research in this area has focused on ornaments as “handicaps,” which are costly to maintain and therefore more elaborate versions can only be produced by individuals in good condition. Emphasis is often placed on the physiological (e.g., energetic) costs of ornamentation, and from this perspective a particularly elaborate ornament can only be produced by an individual who has characteristics like strong foraging skills or a good immune system (► [“Handicap Hypothesis”](#), this volume). However, the overall costs

associated with producing an ornament are not actually very relevant to the maintenance of signal honesty, and the handicap hypothesis is neither necessary nor sufficient to explain many ornaments (Számádó 2011). Instead of focusing on the costs to each individual of producing their own signal, it is more useful to assess the cost differentials in ornament production. Honest signaling can be maintained when low quality individuals face higher costs to producing high quality ornaments compared to high quality individuals. Punishment of cheaters (e.g., via physical attack) is one such mechanism, although many others have been proposed (Számádó 2011). Ultimately, ornament quality is influenced by a variety of costs and benefits, not all of which are the same for all individuals within a species; in many cases, this can lead to an honest system where ornaments are generally indicative of some underlying individual quality.

## Conclusion

Ornaments are often conspicuous traits that would seemingly be costly in terms of avoiding predators, and as such have been of interest to biologists since the origin of evolutionary thinking. Indeed, such characteristics helped to provide the impetus for Darwin to develop his theory of sexual selection. Much of the research on ornamentation has focused on identifying ornaments across species via mate choice experiments, isolating the mechanisms by which ornaments can evolve, and identifying if and how ornaments can function as honest indicators of individual quality. In studying ornaments, biologists have learned about the nature of evolution and have helped to explain the existence of some of the most impressive phenotypes in the animal kingdom.

includes the plated and spiked stegosaurs; the armored, spiked, and sometimes club-tailed ankylosaurs; the massive duckbilled hadrosaurian ornithopods; the thickly dome-headed pachycephalosaurs; the elaborately horned and frilled ceratopsians; and all of their respective basal relatives. Distinguishing features used to characterize ornithischians among other dinosaurs include a unique, midline jaw bone known as the prementary (forming the bottom half of the beak), a medially inset tooth row in most cases, and a caudally oriented pubis (a hip bone), among many others (Weishampel 2004).

With fossilized skeletal remains being the only glimpse into dinosaur biology, researchers use many different clues in skeletal morphology, brain endocast morphology (see below), footprints, dental wear patterns, and pathologies, among others, to speculate various aspects of their past behavior and cognitive abilities. Without the direct knowledge given by observational research and experimentation of live animals, speculation of ornithischian dinosaur behavior among many researchers is subject to countless debates regarding all of its attributes. In terms of intelligence and cognitive ability, it is quite clear that a majority, if not all, of ornithischians were largely unintelligent creatures based on relative brain size (see below). Discussions then usually resort to the question of how intelligent the dinosaurs were relative to each other and how would they use that certain amount of intelligence to perform based on instinct, to function properly, to evade predators, and possibly to communicate with one another in a herd setting (Hopson 1977).

## Ornithischia

Ali Nabavizadeh  
Cooper Medical School of Rowan University,  
Camden, NJ, USA

## Introduction

Ornithischian dinosaurs (Fig. 1) form an extinct group of diverse megaherbivores that dominated the Mesozoic Era roughly between 200 million and 66 million years ago. This extensive clade

## Brain Endocasts and Encephalization Quotient (EQ)

Due to the overall lack of actual dinosaur brains in the fossil record, researchers have relied on brain endocasts (i.e., endocranial brain cavity) to form a general understanding of brain morphology to, in turn, speculate on cognition and behavior. Because an endocast is an outer molding of a combination of the brain and all of the tissues

**Ornithischia, Fig. 1** Fossil skeletons of various ornithischian dinosaurs portraying distinguishing features. (a), *Stegosaurus* (a stegosaur) in oblique caudal view portraying four large tail spikes and plates along its back; (b), *Edmontonia* (a nodosaurid ankylosaur) in oblique rostral view portraying extensive body armor and large spikes protruding rostrolaterally; (c), *Parasaurolophus*

(a lambeosaurine hadrosaur) cast skeleton in oblique rostral portraying long, tubular crest used in enhanced vocalization; (d), *Pachycephalosaurus* (a pachycephalosaur) cranium in lateral view portraying large dome-shaped skull roof; (e), *Triceratops* (a ceratopsid ceratopsian) in oblique rostral view portraying large brow and nose horns as well as its large neck frill extending from its

that surround it (i.e., neural tissues [such as meninges], vasculature, etc.), it is not indicative of the absolute morphology of the brain itself (Edinger 1929). Also, due to the variation in the relationship between brain tissue size and endocast size, estimates of brain size can range anywhere between 50% and 95% in dinosaurs (Buchholtz 2012). With this in mind, comparative methods with living animals, either closely or distantly related, are used to make such inferences.

Regardless of the well-known setbacks, the morphology of the endocast is still greatly useful in predicting overall size and shape as well as more localized morphologies of individual anatomical features of the brain. Until recently, endocast studies have relied primarily on moldings and descriptions of cranial specimens that are broken such that the endocast is easily visible. Now, with the help of technological advances in computed tomography (CT) scanning, many are able to describe internal anatomy of dinosaur endocasts with digital volumetric data. For example, the variable relative sizes of the olfactory bulbs in the forebrain give indications of the degree of the sense of smell in these animals.

The primary method of speculation of ornithischian behavior with the use of endocasts is that of the encephalization quotient (EQ) (Jerison 1973; Hopson 1977; Buchholtz 2012). The EQ uses a regression of the relationship between brain size and body size to infer levels of cognitive function across animals of different clades relative to one another. Hopson (1977) performed the most extensive study of EQs across Dinosauria and interpreted a great deal regarding relative dinosaur intelligence. As dinosaurs are a member of the clade Archosauria, Hopson (1977) compares them to other archosaurs that are alive today, such as crocodilians and birds, as well as with mammals, to see comparatively where dinosaurs

are situated. In these analyses, larger brain sizes in dinosaurs ( $>1.0$ ) relative to body size are typically thought of as a proxy for a more advanced and complex cognitive ability and behavioral spectrum (Buchholtz 2012). Some of Hopson's (1977) results are used in the descriptions of EQs in various ornithischian clades below. With these studies, it is imperative to also be mindful of relative sizes of different regions of the brain as well, as these can also have an effect on the overall EQ.

## Functional Morphology

Studies in functional morphology of ornithischian dinosaurs also provide a great deal of insight into plausible behaviors among them. For instance, the diverse rounded-to-spade-shaped, denticulate, and often precisely occluding dentition of ornithischian dinosaurs has greatly informed paleontologists and functional anatomists of their past feeding behavior. In accordance with their morphological diversity, macro- and microscopic dental wear patterns have provided direct evidence of true feeding motions of the lower jaw during feeding, including orthal (i.e., dorsoventral, or up-and-down, jaw motion), palinal motion (i.e., caudally oriented, or backward, jaw motion while teeth are occluded), and long-axis rotation of each side of the jaw at the prementary joint (Mallon and Anderson 2014; Nabavizadeh and Weishampel 2016). These feeding motions vary both between and among clades of Ornithischia, and each gives a paleoecological context of the animals' respective time periods (Nabavizadeh 2016). Coprolites (i.e., fossilized dung) have also been used to assess plant material consumed by these animals (Chin 2012).

In addition to feeding mechanics, major evolutionary transitions in locomotive behavior have

**Ornithischia, Fig. 1** (continued) skull. Photographs of specimens were taken by the author at the American Museum of Natural History in New York City, New York (*Tegosaururus*, *Edmontonia*, *Pachycephalosaurus*,

*Triceratops*), and the University of Kansas Natural History Museum in Lawrence, Kansas (*Parasaurolophus*, which is a cast of a specimen at the Royal Ontario Museum in Toronto, Canada)

been described throughout the ornithischian clade as well. Convergent transitions from bipedality to quadrupedality have been described in all major subclades of Ornithischia, and numerous studies have explored the biomechanical nature of these transitions within each group, both with computer modeling (Maidment et al. 2014) and from fossil footprints or tracks. Track sites provide direct evidence of locomotive behavior, as it provides a true account of patterns in movements made by these animals (Farlow et al. 2012). This includes transitions from walking to running behaviors as well as sociality, such as that seen in ornithopod track sites.

Furthermore, distinctive and vibrant anatomical ornamentations adorning the external morphology of many ornithischian groups are also clear indicators of certain behavioral traits, specifically that of weaponry and defense used in intra-specific or interspecific combat (such as in defense against predators). Other external features could have been utilized for communication and display purposes, some of which may have been sexually selected. There has also been much broader speculation into various other plausible behaviors as well, such as those of breeding strategies (Isles 2010) and herd behaviors (Bakker 1986); although, these speculations mostly lack the evidence to support them. Many of the anatomical characteristics are noted in the descriptions of the diverse ornithischian dinosaurs below.

## Ornithischian Evolution

Ornithischians appeared roughly 200 million years ago and diversified rapidly throughout the Jurassic and Cretaceous Periods until their extinction 66 million years ago, at the end of the Mesozoic Era. Among the earliest forms were relatively small, bipedal animals that are believed to have already transitioned to at least a partially, if not fully, herbivorous diet. The basal-most major clade was Heterodontosauridae, which includes genera like *Heterodontosaurus* with specialized skull characteristics, including heterodont dentition (i.e., teeth that differ in shape along the tooth row) with a sharp caniniform tooth on each side

that has been speculated to have possibly been a weapon (Hopson 1977; Farke 2014). Along the ornithischian clade, body-type diversity differentiated, with forms such as the larger thescelosaurines, including *Thescelosaurus*, as well as the two major neornithischian clades, Ornithopoda and Marginocephalia (Boyd 2015).

Ornithopods initially conserved the basal ornithischian morphotype, with small, bipedal herbivores, such as *Hypsilophodon*. As the clade continued to diversify, however, they grew to be much larger, with many of them transitioning into partial or full quadrupedality. Iguanodontians were the major clade of ornithopods that gave rise to the well-known duckbilled hadrosaurs. Early iguanodontians included genera such as *Dryosaurus*, *Tenontosaurus*, and *Iguanodon*, each, respectively, larger than the previous. *Iguanodon* was first described by Mantell (1825) and was the first ornithischian to have ever been described. The duckbilled Hadrosauridae are divided into two major clades: the hollow-crested Lambeosaurinae (including such genera as the tube-crested *Parasaurolophus* as well as the round-crested *Lambeosaurus* and *Corythosaurus*) and the Saurolophinae (including such genera as *Prosaurolophus*, *Edmontosaurus*, *Maiasaura*, and *Gryposaurus*) (Prieto-Marquez 2010). Hadrosaurids included some of the largest ornithischian dinosaurs, some reaching over 40 or even 50 ft long, which would have likely been beneficial in lieu of any major anatomical weaponry when confronted with predators.

Marginocephalia is divided into two major clades. The first of these clades is the dome-headed Pachycephalosauria, which included such bipedal forms as the small *Stegoceras* and the much larger *Pachycephalosaurus*. Pachycephalosaurs possessed greatly thickened and vascularized skull roofs, which debatably might have been used for flank-butting (see below). The other much more diverse clade is the horned and frilled Ceratopsia. Ceratopsians ranged from very small, dog-sized beaked animals, such as *Psittacosaurus*, to moderately larger members with large frilled caudal margin of the skull, such as *Protoceratops* and *Leptoceratops*, to the much larger-bodied and highly derived

Ceratopsidae, divided into the Centrosaurinae (including such genera as *Centrosaurus*, *Styracosaurus*, and *Pachyrhinosaurus*) and the primarily longer-frilled Chasmosaurinae (including such genera as *Chasmosaurus*, *Pentaceratops*, and the most well-known ceratopsid, *Triceratops*).

The diverse groups mentioned above also each present many signs of diverse behaviors and cognitive functions that are specific to individual taxa as well as groups as a whole, and these are described below.

## Stegosauria

Stegosaurs (Fig. 1a), which include the well-known *Stegosaurus*, are Jurassic large-bodied, quadrupedal animals known primarily for their prominent, diamond-shaped plates and sharp, elongate spikes protruding from their backs, tails, and, in some cases, shoulders (e.g., *Kentrosaurus*). They were primarily graviportal animals (i.e., bearing a large amount of weight on thick legs), walking low to the ground and likely foraging on low plant material. A possible exception to this is *Miragaia*, possessing a much longer neck than other stegosaurs, which could have been used in reaching upward for plants. Previous speculation has stated the possibility of frequent upright posture for reaching higher vegetation; however, this has largely been argued against. Stegosaurs are thought to have exhibited a primarily orthal feeding mechanism (Barrett 2001) with possible slight rotation of the jaws at the predentary-dentary joint (Nabavizadeh and Weishampel 2016).

The flat, variably sized plates are large bones known as osteoderms (i.e., bones formed within the skin). These plates have been subject to extensive speculation as to their primary function and even their true arrangement along the midline of the spine. Because of their thin, almost sheetlike morphology, stegosaur plates are not believed to be used as any sort of defensive structure, as it is not suitable for forceful impacts of any kind. Researchers have suggested the plates to have possibly functioned for thermoregulation, due to

the presence of thin grooves along the plates indicating extensive vasculature. Others have challenged this assertion, however, arguing that the variable nature of plate morphology would not be suitable for thermoregulation and that the vasculature is merely indicative of growth of the plates. The plates have instead been suggested to have played a major role in visual display, given their prominence; however, this is also mere speculation.

The spikes projecting from the tails as well as backs and shoulders of stegosaurs are well accepted as having been used in combat. In fact, direct pathological evidence of the use of the four large tail spikes in *Stegosaurus* as weapons has been described with a puncture mark of a spike within the vertebrae of a predator's (*Allosaurus*) tail (Farke 2014). Biomechanical models of the spikes in *Stegosaurus* as well as the much more prominently spiked *Kentrosaurus* have shown that they are able to withstand great forces that would have occurred when struck in combat.

Stegosaurs typically present with relatively very small brains. Most notably, the brain of the large-bodied *Stegosaurus* has been described as being miniscule compared to the size of its body (Buchholtz 2012). This small brain size led early scientists to suggest that an enlarged space in the sacral region might have been evidence for a “second brain” for innervation to the limbs (Marsh 1881) – an assertion that has been since debunked (Giffin 1991; Buchholtz 2012). Hopson (1977) calculated the EQ of *Stegosaurus* to be quite low relative to other dinosaurs (0.56), corroborating with the assumption of a slow herbivorous lifestyle, especially in an animal that walked around low to the ground with lacked speed or agility.

## Ankylosauria

Ankylosaurs (Fig. 1b), best known for its largest taxon, *Ankylosaurus*, were large-bodied, quadrupedal animals that walked low to the ground and likely fed on low-growing vegetation. They are divided into the subclades known as ankylosaurids and nodosaurids, both of which

diversified during the Cretaceous Period. Dental microwear and morphological studies of their small, denticulate teeth and entire jaw system have shown their feeding mechanisms primarily consisted of a combination of palinal jaw movements with long-axis rotation of each side of the jaw at the predentary-dentary joint (Mallon and Anderson 2014; Ősi et al. 2014; Nabavizadeh 2016; Nabavizadeh and Weishampel 2016).

Ankylosaurs are known for their outer covering of thick armor, made up of heavily built, expansive osteoderms that covered the entire animal, from head to tail. This outer coating is nearly irrefutable evidence of a defense mechanism of some sort. It is likely that it is primarily used in defense against predators, as a predator's mouth would not have been able to surround the armor to bite into it. The only likely strategy in which a predator would have more easily been able to bite into an ankylosaur was to flip it over, as the ventral side of ankylosaurs was free of osteoderms. Still, the massively built nature of ankylosaur armor would have greatly reduced the chances of a predator to even attack an ankylosaur.

Ankylosaurs are also characterized by elongate spikes projecting laterally from the sides of their bodies and, in the case of ankylosaurids, a massive club tail. These characteristics are ideal for defense in combat behavior. The laterally projecting spikes in nodosaurids are especially prominent in many cases, and it seems intuitive that they would be amply helpful in combat situations, whether intraspecific or interspecific, especially in defense against predators of any size, although direct evidence is yet to be found. Depending on the taxon, nodosaurid spikes are oriented variable directions. For example, in *Edmontonia* the shoulder spikes are highly exaggerated in size and angled cranially, whereas in *Sauropelta*, the large shoulder spikes are angled dorsally (Carpenter 2012). Whether these variable spike orientations are indicative of differences in defense mechanisms is subject to speculation.

Ankylosaurid tail clubs are made up of extremely dense and enlarged, rounded bone at the tip of an already very ossified series of tail vertebrae. Arbour and Snively (2009) performed a computer modeling study testing the capacity of

an ankylosaur club tail to resist high forces and concluded that ankylosaurid tail clubs would have primarily been effective in later adulthood on impact when swung at a predator. Although club tails are variable, both between taxa and between ontogenetic stages within a taxon, there is still certain amounts of pain that the tail club likely would have inflicted (Arbour 2009; Farke 2014). The impact function of club tails in ankylosaurids would have been assisted by greatly enhanced hip and leg musculature (Arbour 2009; Farke 2014). Intraspecific combat could have also been possible among ankylosaurids. Other functions of the tail club could have been for display; however there is no direct evidence to support this.

In terms of brain morphology, nodosaurids and ankylosaurids show a diversion in hypertrophied sensory organs of the brain. Nodosaurids, such as *Silvisaurus*, show more prominent brain characters that would enhance vision, such as a rounded cerebrum and optic tectum (Eaton 1960; Buchholtz 2012). In contrast, ankylosaurids, such as *Euoplocephalus*, present with enlarged, divergent olfactory bulbs, which corroborate with enlarged and complex nasal passages. Hopson (1977) calculated the EQ of *Euoplocephalus* as even lower than *Stegosaurus* (0.52), also corroborating with an unintelligent, slow, herbivorous lifestyle in an animal that walked low to the ground with little agility.

## Ornithopoda

Ornithopods consist of a vast range of small- to large-bodied bipedal and quadrupedal herbivores, most notably the distinctive duckbilled hadrosaurs (Fig. 1c), such as *Parasaurolophus*, *Corythosaurus*, *Lambeosaurus*, and *Edmontosaurus*, as well as other iguanodontians, such as *Iguanodon*. The small-bodied ornithopods, such as *Hypsilophodon* and *Dryosaurus*, are bipedal animals with small, rounded teeth with primarily orthal feeding mechanisms with slight mandibular rotation (Weishampel 1984; Nabavizadeh and Weishampel 2016). As ornithopods diversified into the much larger iguanodontians, including hadrosaurs, there is a transition to a graviportal,

quadrupedal gait, and a major palinal component is implemented into their feeding mechanism in addition to long-axis rotation of the mandibles (Nabavizadeh and Weishampel 2016). Other studies have suggested the possibility of a form of cranial kinesis called “pleurokinesis” might have also been a key component in ornithopod feeding mechanisms (Weishampel 1984; Norman and Weishampel 1985), but more recent studies have challenged this notion (Rybczynski et al. 2008; Holliday and Witmer 2008; Cuthbertson et al. 2012). The immensely packed tooth batteries in the advanced hadrosaurs are also indicative of likely extensive feeding behaviors.

Notable characteristics of lambeosaurine hadrosaurs in particular are their incredibly diverse hollow cranial crests. Although these crests have previously been speculated to have been used in combat, it is now well known that they were used as resonators for vocalized communication between members of a specific taxon (Weishampel 1981). The long, tubular crest of *Parasaurolophus* is the most well-known case of this, with hollow cavities that pass through the crest and lead to the voice box, acting like a trumpet to amplify and enhance calls made by the animal (Weishampel 1981). Other morphologies of this crest also exist, such as the rounded nature of the crests in *Corythosaurus* and *Lambeosaurus*.

In terms of self-defense in an encounter with predators, most ornithopods do not possess any external anatomical features that could be used in combat. Basal iguanodontians, such as *Iguanodon*, are known for their conical thumb spikes that have been speculated to have been a special defensive structure against predators, although they could also have been used in feeding or mating aid (Farke 2014). Besides this exception, however, the lack of defense structures was likely compensated by the immense body size of many hadrosaurs, such as *Edmontosaurus* and, the largest of all, *Shantungosaurus*. Evidence from trackways and nesting sites of a hadrosaur known as *Maiasaura* have portrayed a great likelihood of sociality and communal living among these animals as well (Horner 2000), which would have

also been greatly beneficial in defense against predators.

Endocast morphology in ornithopods has offered clues into their active lifestyles and into their bipedal to quadrupedal nature, which has corroborated with inferences of stature using limb bone morphology (Buchholtz 2012). The ornithopod hypsilophodontid *Leaellynasaura* exhibits clear optic lobes that researchers speculate suggested high visual acuity in dark winters (Buchholtz 2012). Hopson's (1977) EQ calculations ranged from just below 1.0 in the earlier, mid-sized *Camptosaurus* to variably up to about 1.5 in the larger iguanodontian dinosaurs, such as *Iguanodon* and hadrosaurs. These results suggest a higher level of complex cognition compared to the armored thyreophorans (i.e., the stegosaurs and ankylosaurs). This is likely, again, due to the fact that ornithopods lack any defense mechanisms anatomically and therefore might have also needed to rely on sociality and communicative herd behaviors in order to survive, in addition to sensory acuity, faster running speeds, and much larger body sizes.

## Pachycephalosauria

Pachycephalosaurs, such as the well-known *Pachycephalosaurus* (Fig. 1d) and *Stegoceras*, are bipedal, orthal-feeding herbivores with characteristic dense, dome-shaped skulls. The dome is created by the frontal and parietal bones on the dorsal surface of the cranium and has been speculated to have been used in intraspecific head-butting combat, analogous to that of sheep and goats. One histological study argued against this due to certain distributional patterns of stress-induced bone cells within the dome (Goodwin and Horner 2004). However, other studies have noted there is still reason to believe that pachycephalosaurs could have used their domes for defense in some form (Farke 2014), such as possible flank-butting behavior (Carpenter 1997). Head-to-head butting combat is still plausible, although less so due to the small contact point required for accurate ramming (Farke 2014). Although complete cranial material of

pachycephalosaurs is relatively rare, braincase specimens of pachycephalosaurs are especially numerous due to their preservation within their thick-domed crania. Most prominently, pachycephalosaur braincases display large olfactory bulbs, suggesting a strong sense of smell.

## Ceratopsia

Ceratopsians (Fig. 1e) have arguably the most extravagantly ornamented skulls of any dinosaur. The most well-known ceratopsian by far is the three-horned *Triceratops*, which also happens to be the last and largest-bodied ceratopsian of all. Ceratopsians are known for their expansive frills that extend from the parietal and squamosal bones in the back of their skulls. The most basal ceratopsians, such as *Chaoyangosaurus*, *Yinlong*, and even the common *Psittacosaurus*, do not possess prominent frills; however, they do possess a characteristic rostral bone, which is a midline upper jaw bone unique to ceratopsians that opposes the prementary of the lower jaw. These basal ceratopsians were very small, bipedal herbivores ranging from the Jurassic into the Cretaceous, when the vast majority of ceratopsian diversity expanded. Notably, *Psittacosaurus* endocranial anatomy suggests an enhanced sense of smell (Buchholtz 2012), likely used for foraging. Furthermore, the hornlike structures projecting laterally from the cheeks of *Psittacosaurus* have been speculated as flank-butting weapons, although this is uncertain (Farke 2014). *Leptoceratops* and *Protoceratops* are two quadrupedal Cretaceous ceratopsians with much more distinctive frills extending caudally from their skulls. They were larger than their basal relatives and possessed much more robust beaks which, along with feeding, could have been used for biting predators in self-defense. They also possessed incipient nose horns that have been loosely speculated to have been used in combat (Farke 2014). These forms are predecessors to the derived and highly diverse ceratopsids and primarily fed with a palinal motion of the jaw (Varriale 2016).

The large-bodied, quadrupedal ceratopsids are divided into the Centrosaurinae (e.g.,

*Centrosaurus*, *Styracosaurus*, and *Pachyrhinosaurus*), which mostly have a relatively shorter frill and a single nose horn and short brow horns (with exceptions), and the Chasmosaurinae (e.g., *Chasmosaurus*, *Pentaceratops*, and *Triceratops*), which mostly have a relatively longer frill and two large brow horns and one short nose horn (with exceptions). Ceratopsids are known to have implemented a major palinal component into their feeding mechanisms in addition to orthal slicing (Varriale 2011; Mallon and Anderson 2014; Nabavizadeh and Weishampel 2016).

The elaborate cranial ornamentation worn by ceratopsids has been subject to a plethora of in-depth studies elucidating both their function and their role in phylogenetic relationships within the Ceratopsidae. Studies that have explored various possible functions of ceratopsian horns and frills include those exploring the possibility of intraspecific combat (Farke 2004; Farke et al. 2009), possibly in competition for mates in many cases and defense against predators (Farke 2014). The frills in ceratopsians could have been used for extra defense of the neck, as most were too large and wide for any predator to wrap their mouths around. In addition, they possessed hornlike knobs and spikes along the edges of their frill for extra defense, which is exaggerated especially in centrosaurines like *Styracosaurus*. The immense, keratin-covered, and sharp brow horns of most chasmosaurines like *Triceratops* are ideal for piercing any animal in combat and defense, as is the single large nose horn in centrosaurines like *Centrosaurus* and *Styracosaurus*. One unique centrosaurine known as *Pachyrhinosaurus* is characterized by a large plateau-shaped boss structure on its nose in place of a horn that was likely used in more forceful ramming behavior rather than piercing (Farke 2014). In terms of intraspecific combat, this type of behavior can be analogized to that of sheep and goats that ram heads in combat, just as it can also be analogized with pachycephalosaur fighting. Certain cranial pathologies of *Triceratops* and *Centrosaurus* specimens have been attributed to combat behavior as well, with variable patterns in bone growth suggesting varied fighting styles (Farke 2014).

Hopson (1977) calculated the EQ values of both *Protoceratops* and *Triceratops*. Although the exact values are not identified in the text for these two taxa, the two graphs provided show the EQ of *Protoceratops* to be roughly around 0.9 and the EQ of *Triceratops* to be roughly 0.7. At first glance, it seems counterintuitive that an earlier, much smaller ceratopsian would have a lower EQ value. However, *Protoceratops* did not possess nearly as effective of defensive structures as *Triceratops*' large horns. In turn, *Protoceratops* needed to rely more upon speed and sensory acuity to evade predators rather than fighting back with weaponry like *Triceratops* (Hopson 1977).

## Conclusion

Although it is extremely difficult to decipher behavior and cognition in the extinct ornithischian dinosaurs with direct evidence, there are still many clues that researchers have used to elucidate certain aspects of the lifestyle of these animals. Skeletal morphology, brain endocast morphology, tooth wear, footprints, and pathologies, among others, all play key roles in aiding in analyses of behavior and cognition, both directly and indirectly. Ornithischian dinosaurs, along with sauropodomorphs and a select few theropods, made up the vast majority of the megaherbivores of the Mesozoic ecosystems and contributed immensely to faunal and environmental fluctuations. Because of this, continued research elucidating aspects of their functionalities, sociality, and intelligence can help provide important insights and context for the state of the ecosystems of today.

## Definition

Female reproductive cells that typically divide and develop to form a genetically distinct organism following fertilization by a male cell (e.g., sperm).

## The Female Gamete: A Highly Specialized Cell with Additional Components

Oogenesis – the development of the ova – is a dynamic process whereby germ cells undergo meiotic divisions to produce cells of a haploid state ( $n$ ). Evidence from studies of different species brings light to endless variations on the complex happenings during oogenesis. Despite variation in the process of ovum development among taxa, there is one common theme: the product is a highly specialized cell, which (when activated) commences the events of embryogenesis. Indeed, an ovum that took weeks to months to develop can be extraordinarily transformed within minutes during fertilization. In this entry, the term “ova” is restricted to an ovulated female gamete and, unless otherwise stated, the information provided is drawn from mammalian examples.

The ovum is ovulated as a “complex” that consists of three components: (i) the cumulus layer, consisting of several layers of ovarian follicular granulosa cells embedded in an extracellular matrix composed of hyaluronic acid; (ii) the specialized extracellular matrix, or zona pellucida (ZP), consisting of glycoproteins that are synthesized and secreted by the oocyte; and (iii) the oocyte (pre-ovulation) or ovum (post-ovulation), which is arrested at metaphase of meiosis II within the ovaries (Evans and Florman 2002).

Each of these three components has a specific function prior to and/or during fertilization. The thousands of cells that make up the cumulus layer support the oocyte before and ovum after ovulation. Postovulation, the “cloud-like” cumulus layer facilitates both the ovum’s transit into the oviduct and the passage of sperm to the ovum surface. As way of minimizing the risk of polyspermy (i.e., entry of the ovum by  $\geq 2$  sperm, which results in ovum mortality), the cumulus cells secrete substances that control the number of sperm that interact with the ZP via processes of chemotaxis and mediation of sperm motility (Oren-Benaroya et al. 2008). A prerequisite for sperm to be able to pass through the ZP is the acrosome reaction (AR), which is calcium-dependent exocytotic event that results in the

fusion of the sperm acrosomal membrane with the sperm plasma membrane. The widely accepted view that the AR is primarily induced by interaction with the ZP has recently been reconsidered with evidence suggesting that the cumulus cells “prematurely” induce the AR as a means of limiting the number of viable sperm that reach the ovum (Jin et al. 2011). AR sperm penetrate the ZP, enter the perivitelline space (i.e., the space between the ZP and the ovum’s plasma membrane), then adhere to and fuse with the plasma membrane (Evans and Florman 2002). Following this, ovum activation occurs and embryonic development is initiated. Research in ovum activation has focused on the mechanism by which sperm evoke oscillations of cytosolic calcium concentrations in the ovum; however, the specific mechanism through which a sperm activates an ovum remains largely unknown and highly controversial (Xu and Yang 2017). Ultimately, the fusion of the ovum and sperm results in the formation of a diploid ( $2n$ ) zygote. The second meiotic division of the ovum, with separation of chromatids, occurs shortly after fertilization. Later, the zygote will divide mitotically, eventually giving rise to a multicellular organism.

## Female Responses and Behavior: Implications for Ova Form and Function

Female behavior and physiological responses to their environment can profoundly influence ova form and function. For example, in many species, mothers are expected to adjust the size of their propagules to align with the environmental conditions to which those offspring will be exposed (Mousseau and Fox 1998). More specifically, life-history theory predicts that females should increase their investment in offspring quality if those offspring are at a high risk of encountering adverse environmental conditions. In several fish and amphibian species, larger offspring have been shown to fair better under adverse conditions and high predation rates. As a demonstration of phenotypic plasticity in ovum form, in these species females will adaptively tailor ovum size to match the environment that their offspring will

encounter after birth (Mousseau and Fox 1998). Remarkably, females may also mediate their investment in ova size based on the level of help that they will receive to care for their young (i.e., as demonstrated in a cooperatively breeding cichlid; Toborsky et al. 2007).

It has also been shown that female mating behavior can influence the evolution of ova function and the relative ease at which they may be penetrated and fertilized by sperm (reviewed: Firman 2018). Successful fertilization requires the co-occurrence of a sufficient number of competent sperm within the vicinity of the ovum. If females have mated polyandrously (i.e., with  $\geq 2$  males), they may be presented with the opportunity to “select” the sperm of a high quality or compatible male (“cryptic female choice,” a form of postmating sexual selection; Firman et al. 2017). In turn, this may lead to the production of better quality offspring and thus improve the evolutionary fitness of females. However, when females do mate multiply, rival males are often forced to compete for fertilizations (“sperm competition,” a form of postmating sexual selection), resulting in intensified selection for increased sperm number and quality. This scenario can lead to what is best described as “gametic sexual conflict,” whereby selection is driving the evolution of increased sperm numbers (“sperm competitiveness”), which in turn leads to an increased risk of reproductive failure resulting from polyspermy and a counteracting female response of increased resistance to fertilization (“ovum defensiveness”) (Firman 2018). Evidence in support of this gametic “coevolutionary arms-race” is accumulating both within and among different mouse species (e.g., Dean and Nachman 2009; Firman et al. 2014).

## Ovaries

Natalie S. Fraser  
The University of Queensland,  
Gatton, QLD, Australia

## Introduction

In domestic animals, ovarian structures producing steroid hormones are integral to reproductive behavior. Although ovarian steroids have other

cognitive functions, these roles are less understood in domestic animals. The ovaries are ovoid, paired female gonads that are positioned anatomically in close proximity to the mammalian kidney. Ovarian size and shape is species dependent and relative to the functional structures present such as antral follicles or a corpus luteum. The ovary is comprised of an outer tunica albuginea, ovarian cortex, and ovarian medulla. In most species (except mares), oocytes and functional corpora lutea are found in the ovarian cortex. The medulla is composed of dense connective tissue and provides vascular, nervous, and lymphatic supply. The anterior portion of the broad ligament attaches to and supports the ovary; this portion of the ligament, the mesovarium, provides blood vessels, lymphatics, and nerves to the ovary. The utero-ovarian ligament provides structural attachment to the uterine horn. The ovary is partially or completely covered by the infundibulum of the oviduct at the time of ovulation to allow capture of the released oocyte.

## Main Text

Reproductive behavior is programmed during prenatal development and is the result of normal development chromosomal, gonadal, and phenotypic sex. The brain in mammals develops into a female phenotype unless exposed to hormones from the developing gonad. In female mammals, maternal estradiol and estradiol from the developing gonad is bound by  $\alpha$ -fetoprotein and prevented from crossing the blood-brain barrier preventing masculinization of the hypothalamus such that both tonic and surge centers develop. Thus, the female embryo brain becomes fully feminized. Historically, the feminization of the brain has been considered a default pathway, but recent evidence supports the active repression of masculinization via DNA methylation pathways (Nugent et al. 2015). Presence of gonadal steroids (estradiol, progesterone) is obligatory for normal female reproductive behavior which occurs in a cyclical fashion referred to as the estrous cycle.

The steroid hormones responsible for female reproductive behavior are estradiol and progesterone. Estradiol, produced by developing follicles on the ovary, either allows the expression of estrus or enhances the expression of estrous behavior. Estrus behaviors will vary dependent on the species, but the hallmark behavior is willingness to be mounted by the male (Senger 2012). In the cow, estrus may be preceded by increased ambulation, vocalization, mounting other periestrus females, and formation of sexually active groups. Mares exhibit characteristic behaviors such as tail raising, clitoral winking, tilting of the pelvis/leaning into the stallion, and urination. Sex hormones facilitate reproductive behavior via receptors in the hypothalamus; however, other brain functions and nonreproductive behaviors are also influenced by estrogens including fine motor control, motor coordination, pain, mood regulation, cognitive function, cardiovascular regulation, neuroprotection, and others (McEwen et al. 2012). Nonreproductive behaviors are produced through estrogen's actions on several other brain areas beyond the hypothalamus including the spinal cord, cerebellum, nigrostriatal and mesolimbic system, amygdala, hippocampus, cerebral cortex, and brainstem (McEwen et al. 2012).

In contrast, progesterone is produced by the corpus luteum formed after ovulation of a dominant follicle(s). Progesterone inhibits estrous behavior such that the female is not receptive to mating attempts during the luteal phase of the estrous cycle, even if other large follicular structures are present. The exception to this is the bitch; preludeinization of follicles results in standing estrus in the face of rising serum progesterone levels. Diestrus behavior may range from passive avoidance of males to outright aggression towards male animals to avoid mating attempts. If maternal recognition of pregnancy does not occur, luteolysis is initiated by the production and release of prostaglandins from the endometrium, allowing the female mammal to return to estrus and sexual receptivity.

Historically, it was accepted that prenatal development resulted in specific male or female

neural pathways that were activated by gonadal steroids to result in male or female reproductive behavior. This dogma has been questioned at least in part by studies that demonstrate that adult mice are capable of displaying reproductive behaviors of either sex and suggested that pheromones interpreted through the vomeronasal organ also play a significant role in expression of reproductive behaviors (Dulac and Kimchi 2007).

## Conclusion

Hormones produced by developing ovarian structures result in a cyclical pattern of reproductive behaviors in female mammals. In the event of pregnancy, this cyclical pattern is interrupted and the female is nonreceptive to further mating attempts until after parturition and resumption of ovarian activity. Understanding of the length of the estrous cycle in various species and subsequent interpretation of estrous behaviors is an important aid in breeding management of common domestic species.

## Overdominance

### ► Heterozygote Superiority

## Overdominance Hypothesis for Male Homosexuality

Andrea S. Camperio Ciani  
University of Padova, Padova, Italy

## Introduction

The complete definition of overdominance according to the Merriam-Webster dictionary is “the condition wherein a heterozygote produces a phenotype more extreme or better adapted than that of the homozygote.” In other words, overdominance produces a balanced polymorphism where the heterozygote has a greater phenotype value and it is more fit than the homozygous state for either of the alleles that it comprises. Hence, overdominance can also be described as heterozygote advantage, wherein heterozygous individuals have a higher fitness than homozygous individuals.

To clarify the effect of overdominance, the example of sickle cell anemia can be considered. Consulting the American Heart, Lung, and Blood Institute guidelines, it appears that this condition is determined by a single polymorphism. Sickle cell anemia results in an abnormality in the oxygen-carrying protein hemoglobin; homozygote carriers develop a specific syndrome with number of health problems. Carrier of these deleterious alleles has lower life expectancy, with homozygotes dying at early age.

It should be noticed that if a certain trait or behavior is detrimental to the reproductive success, or fitness, of an organism, one would not expect it to persist in the population. Natural selection should progressively eliminate it. Then, in an evolutionary perspective, the following population genetic question arises, why such deleterious disease does not disappear generation after generation, since the carriers of the alleles mostly die leaving less offspring than healthy individuals.

The answer is because this allele also yields resistance to malaria. Thus, in those population living in regions where malaria has exerted a

strong selective pressure, sickle cell anemia allele has been selected for its conferred in heterozygous individuals' partial resistance to malaria; these individuals have fewer physiological effects of sickle cell anemia; thus they survive better and leave more offspring than healthy individuals that on the contrary die of malaria. Hence the alleles for sickle cell anemia remain in balanced selection in the population due to the advantage carried by the heterozygote individuals on both homozygote ones. Alleles producing sickle cell anemia express themselves with an overdominance mechanism.

## Overdominance in Male Homosexuality

The hypothesis of a balanced selection has long been advocated by scientist trying to come to terms with the Darwinian paradox of human homosexuality and especially male homosexuality. Also in this case it has been since long clarified as a genetic component in our species. Homosexuality runs in families, and homozygotic twins have more than expected concordance in homosexual orientation. Homosexuality is not strictly genetically determined; however the heritability is between 0.3 and 0.7. However, genetic components can never be considered as strict determinants of homosexuality, and they should always be interpreted as acting within the frame of an environmental background that may also strongly contribute to sexual orientation in individuals (Camperio Ciani et al. 2015).

The more recent debate has considered a variety of selection mechanisms for homosexuality. Direct selection was rapidly dismissed in the case of male homosexuality homosexual reproduce far less than heterosexuals. The most promising mechanisms were then based on overdominance, on sexually antagonistic selection, and other selection modes including maternal effects and genomic imprinting, possibly involving epigenetic activity (Gavrilets and Rice 2006; Camperio Ciani et al. 2008).

At first Miller (2000) proposed an overdominance hypothesis for maintenance of male homosexuality in the population, hypothesizing that

individuals heterozygous for the feminizing alleles might make heterosexual carriers of the alleles better fathers and more attractive mates due to greater sensitivity, empathy, tendermindedness, and kindness, while homozygous individuals would develop homosexuality, but this was not further tested at the time. Meanwhile sexually antagonistic selection hypothesis came later suggesting that a gene that is detrimental to fitness in one sex could be maintained so long as it is beneficial to the other sex.

## Empirical Studies

Now it is difficult to trace directly genes influencing homosexuality in humans, even if recent studies seem to have identified some of them. However, without the need to genotype individuals, it is still possible to test the overdominance hypothesis on male homosexuals by verifying its predictions. For homosexuality being the expression of an overdominance mechanism, it should be expected to find an increased number of homosexual relatives and an increased number of individuals with increased fitness (heterozygotes) both in the paternal line and in the maternal line of the pedigree for a homosexual proband (King et al. 2005; Gavrillets and Rice 2006). The overdominance prediction contrast with the sexually antagonistic selection hypothesis that suggests that homosexuality is a male by-product of alleles than in females leads to an increase of fecundity (as compared to the population baseline fecundity under study) and that these genes are partially linked to the X chromosome (Camperio Ciani et al. 2004). In the sexual antagonistic hypothesis, it is expected to find an increased number of homosexuals and an increase in fecundity only in females only in the maternal line in pedigrees of the homosexual probands. The prediction generated by the competing hypothesis could be tested in pedigree analysis of homosexuals, through questionnaires.

Some empirical studies have indeed reported a generalized fecundity increase in other members in the pedigrees of male homosexual probands,

independently of the maternal or paternal line (King et al. 2005; Schwartz et al. 2010). Rieger et al. (2012), further based on the same dataset by Schwartz et al. (2010), found also a fecundity higher than expected in brothers of male HS as compared to brothers of the control group, leading some support to the overdominance hypothesis.

In contrast, Camperio Ciani et al. (2004) found that homosexuals are significantly more represented in the maternal line of homosexual probands and that only mothers and maternal aunts show a significant fecundity increase as compared to baseline population fecundity, hence supporting a sexually antagonistic mechanism for the maintenance of male homosexuality (Camperio Ciani et al. 2004). These results suggesting a sexually antagonistic hypothesis were replicated over again in different populations on male homosexuals (Camperio Ciani and Pellizzari 2012; Gavrillets and Rice 2006) and also in bisexuals (Camperio Ciani et al. 2009) and are opposed to the prediction for overdominance mechanism. Subsequently, also the data by Schwartz et al. (2010) were reanalyzed by Camperio Ciani and Pellizzari (2012), pointing also in this dataset to a previously unnoticed larger maternal-line female fecundity suggesting a sexually antagonistic selection rather than an overdominance mechanism.

## Population Dynamic Models

Mathematical models exploring the dynamic and equilibria of human male homosexuality were stimulated by some of these competing hypotheses and predictions. First, Gavrillets and Rice (2006) developed single-locus models (the effect of a single genetic factor), and then Camperio Ciani et al. (2008) developed multi-loci models (considering the effect of two or more genetic factors), either in the autosomes (the nonsexual chromosomes) or in the X chromosome. These authors have explored various selection modes in each case, under the assumption of random mating. They examined for each model the range of selection parameters which would guarantee a

stable polymorphism, hence the persistence of the trait in the population. The results showed that single-locus models are all largely unstable as their parameter ranges are too narrow to allow for stable polymorphism under the normal variability of population conditions (Gavrillets and Rice 2006). All these models due to their instability lead to either fixation or extinction of the genetic factors, contrary to the empirical requirement that suggests that homosexuality is relatively stable in human populations.

For multi-locus models, the overdominance models were shown to generate polymorphic equilibria compatible with the stability requirements for male homosexuality. However, these models always account incorrectly for the pedigree asymmetries highlighted in empirical studies, as they predict increased fecundities in both pedigree line (maternal and paternal) and regardless of sex. Fecundity enrichments in the families of male homosexual probands have been shown not to occur in such a generalized way but only asymmetrically in maternal-line females. Hence the overdominance selection mode was excluded from the possible maintenance mechanisms for male homosexuality in the population (Camperio Ciani et al. 2008).

Sexually antagonistic selection on the contrary met all empirical predictions (Camperio Ciani et al. 2008). The analysis of the sexually antagonistic model with an autosomal and an X-linked allele emerged as the simplest model, capable of meeting all the empirical requirements assessed in male homosexuality studies. In this mathematical model, the researchers found polymorphism stability at low frequency as predicted, with no extinction or fixation of the genetic factors in wide ranges of increased female fecundity and reduced reproductive success of homosexual males. The X-linked sexually antagonistic model describes all the correct pedigree asymmetries in the maternal line of homosexual males, resulting with a higher than patriline frequency of homosexuality in the males and a higher than patriline fecundity in the females (Camperio Ciani et al. 2008, 2015). Interestingly, a fecundity increase in paternal aunts of heterosexuals, as compared to

homosexuals, was also predicted in the sexually antagonistic models and later observed in empirical data (Camperio Ciani and Pellizzari 2012), strengthening the heuristics of these models. To further confirm the predictions of the sexually antagonistic model of two genetic factors one on the X chromosome and one on the autosomes, a large team of researchers screened a wide sample of homosexual brothers using genetic whole genome analysis (GWAS). The results confirmed, as predicted, a significant signal on chromosome number 8 (autosome) and the X chromosome (Sanders et al. 2015).

The overdominance model seems at present less probable in male homosexuality; however this is not so for female homosexuality. Recent data based on a pedigree analysis of over 30,000 individuals focusing on female homosexuality confirmed that female homosexuality runs in families and has a genetic influence and lesbians have a significant reduced fecundity. This study showed further that lesbians are more frequent in both sides of the pedigree of lesbian probands, and individual with increased fecundity are more frequent in both sides of the pedigree, thus balancing the reduced fecundity of lesbians. These results confirm empirically for female homosexuality the predictions of an overdominance mechanism (Camperio Ciani et al. 2017). It should be noted that in the case of females, an X-linked sexually antagonistic model and an overdominance model partly overlap since females contrary to males are diploid for the X chromosome.

## Conclusion

Male homosexuality is at present less likely explained by overdominance mechanisms. A sexually antagonistic selection model, for a multi-locus factor with at least an X-linked locus, provides a closest adherence to the empirically known patterns for male homosexuality. Overdominance, on the contrary, seems probable for female homosexuality where the patterns of generalized increase of homosexuality and increased fecundity that is expected in all the relatives of lesbians seem to be empirically confirmed.

### Definition

Overshadowing may be defined by the consequences on behavior, the procedure that produces that consequence, and the mechanisms behind it. The following definition is at the level of behavior and procedure, for theoretical explanations, see below.

The phenomenon of overshadowing refers to a decrement in acquired conditioned responses produced by the training of two conditioned stimuli (CSs) together (i.e., in compound), followed by an unconditioned stimulus (US),  $CSa + CSb \rightarrow US$ , relative to training the stimulus apart,  $CSa \rightarrow US$  and  $CSb \rightarrow US$ . In this situation, the CS with more salience will be the one that generates higher conditioned responses at testing.

### Introduction

Overshadowing often represents how animals learn in the natural context when different stimuli presented at the same time compete for attention. An example of this is when a dog is fed, in front of him, the dog can see the food as it falls into his bowl, can smell it, and hear the sound it makes as it falls. All these stimuli compete to overshadow the others.

In addition to overshadowing, other interactions between CSs can also produce decrements in response (Miller and Escobar 2002). These situations can be classified as competition, when the reduction in responding results from training the CSs together in the same phase, as in

overshadowing, blocking (Kamin 1969), and relative validity of cues (Wagner 1968). Alternatively, interference rather than competition is called to the reduction in responding that results from training two CSs with an US, but at separate times (i.e., in different phases of training; e.g., Miguez et al. 2012).

In the case of overshadowing, two CSs are presented simultaneously followed by the US, one of these CSs will have the characteristic of being more intense or salient in comparison with the other CS. During the test phase, when they are presented separately, the more intense CS will generate a greater conditioned response (CR).

In some situations where two stimuli are presented at the same time, the overshadowing phenomenon fails to be found, contrary to what is expected, those stimuli end up potentiating. In potentiation (e.g., Urcelay and Miller 2009) the presented CSs, for example, smell and taste stimuli, can generate a higher CR compared to when they are presented separately, which is contrary to the overshadowing phenomenon.

Overshadowing is a phenomenon observed in different learning tasks and species, for example, instrumental conditioning with rats (Pearce and Hall 1978), aversive conditioning with rats (Wheeler and Miller 2007), spatial learning with rats (Sánchez-Moreno et al. 1999), landmark learning in pigeons and humans (Spetch 1995), appetitive conditioning with rats (Holland 1999), nictitating membrane response with rabbits (Kehoe 1982), taste aversions in humans (Okifuji and Friedman 1992), and antinociceptive response in rats (Illich et al. 1994).

### Overshadowing: From Pavlov to Today

Overshadowing was first observed by Ivan Pavlov (1927), who is considered one of the great exponents of psychology, responsible for the foundation of the theories of behavior and learning. In one of the many experiments carried out by Pavlov and his team, described in his text *Conditioned Reflexes: An Investigation of the Physiological Activity of the Cerebral Cortex*, they observed a phenomenon occurring in stimulus compounds.

When the compound's stimuli were presented individually, one of them was overshadowed by the other. This happened independently of the number of reinforcements.

For example, in one of Pavlov's experiments, a compound of stimuli was presented to a dog: a sound with a light, both were paired with food. When the light stimulus was presented individually it was ineffective because it did not produce any responses. On the contrary, the compound did produce a conditioned response. This was repeated in another experiment; in this case, thermal and tactile stimuli were used. When the two stimuli were presented separately, only the tactile stimulus provoked a conditioned response, while the thermal stimulus did not. Pavlov and his team determined that these differences in the conditioned response were related to the difference in the strength or intensity of the stimuli, so tactile stimuli should be considered stronger than thermal stimuli, and auditory stimuli stronger than visual stimuli. Thus, the stimuli with the characteristic of being stronger or intense overshadowed the stimulus characterized as less strong such that the latter does not generate an association. However, when the less intense CS was presented separately and was reinforced, over time, a conditioned response was generated (Pavlov 1927).

With the development of cognitivism, learning theories were adapted to integrate stimuli compounds in the associations between CSs and USs, attentional processes, and neural models, which impacted the theoretical models of overshadowing.

## **Overshadowing Research: Phenomena and Models**

Various models have tried to explain the phenomenon of overshadowing; these can be separated into two groups, those that focus on acquisition and those that focus on performance.

### **Acquisition-Focused Models**

Rescorla and Wagner (1972) explain overshadowing as a difference in acquisition rate between two CSs. According to this model, the

difference is due to the intensity or salience of each CS, so that faster conditioning would be expected to occur with a strong sound than with a weak sound. In this way, overshadowing occurred when one stimulus was conditioned faster than another during the first tests, so it is traditionally considered an acquisition phenomenon.

Mackintosh (1975) mentions that overshadowing is a consequence of training, since throughout the tests, the subjects learn to ignore the less salient stimuli that, according to his theory, do not contribute anything new to the prediction of the unconditioned stimulus. For this reason, overshadowing can be observed only when there is already training with several conditioning trials. According to the theory of selective attention, when two or more stimuli are present, they compete for the limited attention of the subjects who, on giving their attention to a specific stimulus CSa, will stop paying attention to another stimulus CSb (Mackintosh 1976).

Pearce (1987) stated that the overshadowing is a decrease of the conditioned response that would happen by the generalization that occurs when one of the two CSs presented as a compound is removed. According to this theory, this would occur during the test phase.

Pearce and Hall (1980) argue that the speed of association of CS will decrease as they become good predictors of US since it becomes unnecessary to learn more about the association of CS with US. In the case of overshadowing, the subject generates an association between the compound of CSs and the US, learning that the compound is a good predictor. Once the CSs are presented separately, the associative force of each one of the stimuli will decrease.

### **Retrospective Revaluation and Counteraction of Overshadowing**

Retrospective revaluation is the change of response to a stimulus when another related stimulus is trained (Kaufman and Bolles 1981). Traditional learning-centered acquisition models have problems explaining this phenomenon. For example, in the case of overshadowing, the extinction of one of the CSs will increase the

response to the other stimulus, representing a recovery from overshadowing (Amundson et al. 2008). Another result that challenged models of overshadowing was that this effect counteracted with other phenomena that also reduced responding. For example, training a cue as a blocked stimulus in a blocking training first reduces the ability to overshadow other stimuli later (e.g., Wheeler and Miller 2007). Acquisition-focused models can explain this effect (e.g., Wheeler and Miller 2007).

### **Performance-Focused Models and New Acquisition-Focused Models**

The comparator hypothesis (Miller and Matzel 1988) was the first learning model capable of accounting for retrospective revaluation. This model proposes that associative learning is determined by the contiguity and salencies of the stimuli, focusing on the processing of the information produced in the test and not during the acquisition. In this way, the response to a CS does not reflect the strength of the association between CS and US; instead, it represents the strength of the comparison between the CS-US association with the associative strength of the other stimuli present during training. In addition, this model proposes that at least three associations are learned, which are regulated by the principles of contiguity and salience of the stimuli (the more salient and contiguous the stimuli, the stronger the association). First is the association between the CS A presented in the test and the US. The second is between the CS A and its comparator stimulus (any stimulus present in the environment different from the US and with a strong association with the CS A). And finally, the third association is between the comparator stimulus and the US.

According to the comparator hypothesis, stimuli competition, as in the case of overshadowing, does not arise from a learning deficit but is explained through an error in the expression of the association between the CS A and the US, despite having been encoded during training; i.e., a diminished response to a CS is observed when a second stimulus is present during training and strong CS A-comparator and comparator-US associations are established.

Van Hamme and Wasserman (1994) proposed an associative learning model designed to respond to retrospective revaluation. Their model has similarities with the model of Rescorla and Wagner (1972); for example, both of them focus on the learning processes occurring during acquisition but reject the presumption of the obligatory presence of the CS for the occurrence of changes in associative strength, putting forward the idea that a subject can learn about a CS simply by the presence of a stimulus associated with it. Therefore, it can explain phenomena such as recovery from competition, although it has difficulties explaining counteraction effects of overshadowing (e.g., Wheeler and Miller 2007).

### **Conclusions**

Overshadowing is a key phenomenon when it comes to learning processes and stimuli competition, which has been demarcated with the development of experimental psychology and the study of basic learning processes. This phenomenon has been studied experimentally in both human and nonhuman animals through different tasks and preparations, as well as with different combinations of stimuli. Overshadowing has allowed us to understand how human and nonhuman animals learn from their environment and deal with an enormous number of stimuli present in the context by discerning which CS is the best predictor of the US, saving energy. In that sense, organisms could evolve to learn to ignore stimuli that are not good predictors.

Although almost a century has passed since Pavlov's discoveries, overshadowing continues to be present in the scientific contingency, allowing us to know more about the learning processes through the generation of new research and new lines of investigation.

## Owls

Jennifer Colbourne  
York University, Toronto, ON, Canada

## Introduction

Owls are raptors that make up the order of Strigiformes, subdivided into the “typical owl” (Strigidae) and “barn owl” (Tytonidae) families. There are over 200 species, which can be found on every continent except Antarctica. Species vary in size from the elf owl (*Micrathene whitneyi*), which is the size of a sparrow, to Blakiston’s fish owl (*Bubo blakistoni*), which is the size of a large eagle.

## Morphology and Perception

Nearly all owl species are nocturnal and consequently have eyes that are specialized for vision in poor light. Some species have been demonstrated to have color vision, but there is currently no evidence that any can see in UV or infrared spectra. Owls have forward facing eyes, which provide them with binocular vision. There is evidence that barn owls (*Tyto alba*) structure figure-ground

relationships similarly to primates, indicating some convergent evolution of visual perception (Van der Willigen et al. 2003). However, owls are unique in that their large eyes are tubular shaped and consequently nearly immobile, which is compensated for by a flexible neck able to rotate 270°.

Owls have exceptionally acute hearing. Species of owls with asymmetrical ears, such as barn owls, have been found to be capable of hunting with extraordinary accuracy even in total darkness. Similarly, great gray owls (*Strix nebulosa*) can hunt voles under half a meter of snow using only sound. In order to direct sound toward itself more effectively, the heart-shaped face common to the owl is walled with thick and densely packed feathers, making its face a type of satellite dish. The wing feathers are also specialized for sound reduction in flight, allowing them to surprise their prey (Bachmann et al. 2012).

It has been hypothesized that the ear tufts found on a large portion of nocturnal owls have a camouflage function, giving the appearance of broken branches (Perrone 1981). Most owls are colored in grays and browns with speckling, spotting, and bars to cryptically blend in with their environment. Some owls, like the Northern pygmy owl (*Glaucidium gnoma*), also have “eye spots” on the back of their heads, which appear to confuse mobbing birds (Deppe et al. 2003). Within a single owl species, there can be a wide range of colorations, and there is evidence that these different morphs possess distinct behaviors, differing in a range of dimensions including prey preferences, breeding habitats, dispersal distance, and reactivity (Van den Brink et al. 2012). Some morph types are also more predominant in one sex than the other and change in frequency according to latitude.

## Prey

Owls consume a wide variety of prey, including small mammals, birds, amphibians, reptiles, and invertebrates. However, the majority of owl species’ diets consist primarily of mammals, particularly rodents. Diets also vary seasonally, for

example, with more amphibians or insects consumed at times of the year when mammalian prey is less plentiful.

Compared to females, males consume more birds. This is due to the increased agility of most males, which have a shorter wing length than most females (Lundberg 1986). Some owl species prey on other owl species, for example, Eurasian eagle-owls (*Bubo bubo*) hunt tawny owls (*Strix aluco*), making Eurasian eagle-owls an intraguild predator, as both species predate on the dormouse. In response, tawny owl nest sites are located in Eurasian eagle-owl-free areas or as far as possible from Eurasian eagle-owl nests, resulting in a negative relation of tawny owl density to Eurasian eagle-owl density (Sergio et al. 2007).

Large fluctuations in prey numbers can have a substantive effect on owl population and density. For example, in the boreal forest, the snowshoe hare (*Lepus americanus*) has a population cycle of 10 years. Because the snowshoe hare is the primary prey of great horned owls (*Bubo virginianus*), great horned owls raise larger broods with higher survival rates when snowshoe hare numbers increase (Rohner 1996). This increase in predator numbers is a contributing factor toward a decline in snowshoe hare numbers, which in turn results in a great horned owl population decline. Similarly, vole cycles in Europe affect owl density. It has also been found that Tengmalm's owls (*Aegolius funereus*) adjust their brood sex ratio according to vole cycles, producing more females in low vole density years and more males in high density years, as males have higher mortality when food is limited (Hippkiss and Hörnfeldt 2004).

Unlike most bird species, owl females are heavier than males. According to Lundberg's (1986) starvation hypothesis, females are heavier in order to withstand periods of harsh weather and food shortages when incubating eggs, as they completely rely on male provisioning which may be irregular depending on food availability. Indeed, Lundberg (1986) found that sexual dimorphism was more marked in European owl species according to northerly latitude, where cold weather and food scarcity increases.

## Territoriality

Prey type and density can determine home range size and preferred habitats, resulting in wide variation within and between owl species. However, most owl species live in wooded or forested areas and are sedentary, settling down in one territory after dispersal from their natal area. Still, there are a few select species that are known to be nomadic, such as the short-eared owl (*Asio flammeus*), and others that seasonally migrate large distances, such as the Eurasian scops owl (*Otus scops*).

The ownership of a territory is usually advertised by hooting or visual displays. In years with increased owl population in an area, often due to the prey cycle, the number of owls without territories, or "floaters," increases. Territorial owls appear to prevent floaters from breeding and keep them from entering their territories. The occupation of a territory allows access to prime nest holes and superior spatial knowledge of an area and thereby increased hunting and reproductive success. When the best sites are already occupied, floaters are forced to range over larger and less valuable areas (Rohner 1997). Although leaving a territory is unusual, some owls may relocate ("breeding dispersal") if they are single or have lost their mate, have a low-quality site, or fail to reproduce (Blakesley et al. 2006). Breeding dispersal may also occur during crashes of a prey cycle (Korpimäki 1993).

## Mating

Male owls typically attract mates by singing and may offer nest sites or food. The pair may engage in courtship flights or mutual preening. Most owl species are socially monogamous, at least for the breeding season, and a growing number of studies indicate that they are also genetically monogamous, with nestlings sired by other males extremely rare. It has been suggested that because of the high male parental investment involved in raising owlets, female owls are not willing to risk extra-pair copulations that could lose the support of a mate (Marks et al. 1999). However, in times of great prey abundance, some females will "double brood," that is, start another brood later in the

season with another male, sometimes abandoning care of the first brood to her male partner.

Bigyny, a male with two female partners, is slightly more common in owl males, particularly in high prey availability years. Typically, the male has a “primary” female partner, the first he reproduces with that season, and a “secondary” partner. In Tengmalm’s owls, this secondary partner receives far less prey for her nestlings and consequently has poorer nestling survival, leading some researchers to argue that these secondary partners have been deceived into breeding with a male they believed to be unpaired (Carlsson et al. 1987). Others contend that the females are not deceived as to the mating status of the male but are willing to be a secondary female to a higher-quality male than the monogamous partner of a poorer-quality male, especially as she may receive all of his investment if his primary nest is lost to predation (Sonerud 1992).

## Parental Care

Owlets are born asynchronously over the course of 2 weeks, as eggs are laid and hatched at different times. The result is that nestlings at varying stages of development will be in the same nest. According to Lack’s brood reduction hypothesis (1947), this strategy allows for the greater overall survival of nestlings if food becomes scarce for a period, as only the youngest nestlings will die. Some species will also vary the order of laying male and female eggs, with at least one species (the Eurasian eagle-owl, *Bubo bubo*) preferring to lay females last. As the oldest and largest nestlings have an advantage over the youngest and smallest, there is usually a hierarchy in the nest. According to Penteriani et al. (2010), sibling competition in Eurasian eagle-owls may be reduced by having females born last, since they are larger and heavier.

Most owlets in a nest are full genetic siblings, due to the rarity of extra-pair fertilizations. This means that while owl siblings are in competition for food, their inclusive fitness can be increased by the survival of their siblings through kin selection, since they will share an average of 50% of their genes. Altruism toward kin has been seen among co-nestlings. Satiated owlets will share food with each other, particularly older siblings

with younger (Roulin et al. 2012). Owlets are also known to engage in “sibling negotiation” in the absence of their parents, in which they signal vocally to each other their willingness to compete for food (Roulin et al. 2000). Consequently, nestlings will reduce their own vocalizations in the presence of their parents if one of their siblings has signalled its urgency to be fed, as parents often respond to begging signals to determine which nestling to feed a prey item.

Care of owlets is biparental. While nesting and brooding, the male will provision the female with food. After the female has completed the brooding period, she will join the male in provisioning the chicks by hunting prey, except in the rare cases she begins another brood. Once the owlets have fledged, both parents will continue to aid in their provisioning for several months. During this period, fledglings will occasionally “nest switch,” where they are not only tolerated but fed similarly as their foster siblings (Roulin 1999). Because natural selection should act against the rearing of unrelated nestlings, it is yet unclear why this behavior is tolerated, though it appears to be quite rare.

Several months after fledging, activity levels begin to increase in what has been termed “dispersal restlessness” (Ritchison et al. 1992), and the young owls rapidly disperse away from their natal area, sometimes up to hundreds of kilometers. After this initial dispersal, owls may again make smaller dispersals until they permanently settle into an area. Many species will reproduce after their first year, but others not until their second or third.

## Cognition

Cognitive testing of owls has been very limited. There is some indication that owls have a rudimentary numerical ability, as barn owl nestlings can discriminate between one to four nestmates based on vocalizations (Ruppli et al. 2013). Barn owl nestlings can also discriminate between their mother and father and adjust begging accordingly (Roulin and Bersier 2007). Similarly, several owl species can discriminate between the hoots of neighbors and strangers, which is an important distinction to make as a stranger poses a greater territorial threat (Galeotti and Pavan 1993; Hardouin et al. 2006).

# Conclusion

Most research on owls has taken place within the fields of perception, neuroscience, and ecology, although these investigations have largely been

limited to a few dozen species of Eurasian and North American owls (see Fig. 1). The cognition of these ubiquitous avian predators is a rich and almost entirely unexplored area for future research.

**Owls, Fig. 1** Commonly studied species of owls. (1) Barn owl (*Tyto alba*) located on every continent except the polar regions, (2) Tengmalm's owl/boreal owl (*Aegolius funereus*) located in northern Eurasia and North America, (3) great horned owl (*Bubo virginianus*) located in North and South America, (4) snowy owl (*Bubo scandiacus*)

located in the arctic regions of Eurasia and North America, (5) Eurasian eagle-owl (*Bubo bubo*) located in Eurasia, (6) tawny owl (*Strix aluco*) located in western Eurasia, (7) Ural owl (*Strix uralensis*) located in Eurasia, (8) spotted owl (*Strix occidentalis*) located in western North America. ## Oxytocin

Naomi Ondrasek  
UC Davis, Davis, CA, USA

## Synonyms

Pitocin; Syntocinon®

## Definition

A mammalian peptide hormone, produced in the brain, with wide-ranging effects on numerous aspects of animal physiology and behavior, including reproduction and social interactions.

## Introduction

The physiological importance of oxytocin (OT) was first described in the early 1900s, when biologists discovered that the compound stimulates uterine contractions and lactation. It would take nearly another half century to uncover OT's molecular structure – a nine-amino-acid sequence – and 30 years more to demonstrate OT's potency in regulating social behavior (Lee et al. 2009). Research on OT's behavioral impacts would accelerate substantially in the 1990s, when investigations using rodents implicated OT in pair bonding, parental care, and the evolution of mammalian mating systems. By 2015, this field of study had grown considerably and covered a more diverse range of species – including not only rodents but humans and other primates (Ondrasek 2016). This surge in research revealed OT's contributions to a striking array of physiological, neurobiological, and behavioral

processes. The following entry summarizes some of OT's most well understood functions, as well as its emerging promise as a therapeutic for neuropsychiatric conditions in humans.

## Evolution of the Oxytocin System

Found in mammals, OT is one member of an evolutionarily ancient family of peptides – each consisting of nine amino acids, and thus called nonapeptides – found across invertebrate and vertebrate groups (Lockard et al. 2017). Vertebrate nonapeptides are all derived from vasotocin, which diverged into the vasopressin and oxytocin nonapeptide lineages following a gene duplication event that occurred in early jawed fishes (Goodson 2013). Substitutions at position 8 in the amino acid sequence produced the vasopressin-like and OT-like nonapeptides. The former contain a basic amino acid (lysine, arginine) at position 8, while the latter contain a neutral amino acid. Nearly all vertebrates examined thus far possess at least one OT-like and one vasopressin-like nonapeptide (Gimpl and Fahrenholz 2001).

More than 15 nonapeptides have been identified, suggesting multiple divergence events, but perhaps more notable is the evolutionary stability apparent in nonapeptide structure. For instance, both mesotocin and Leu<sup>8</sup>-OT – the OT variants most commonly found in nonmammalian and mammalian vertebrates, respectively – differ from vasotocin and each other by only one amino acid (Goodson 2013). Such observations suggest that evolution of OT occurred under strong selective pressure to retain the basal amino acid sequence found in vasotocin, possibly due to the integral roles played by OT in critical reproductive functions, which are discussed further below (Anacker and Beery 2013; Gimpl and Fahrenholz 2001). In addition to the structure of the OT peptide, other facets of the OT system are evolutionarily conserved, including the locations of OT-containing neurons and fibers, and the structure of mammalian OT receptors, which are more similar to OT-like receptors in birds and fish than to the mammalian vasopressin receptors (Gimpl and Fahrenholz 2001).

## Structure of the Oxytocin System

### Actions in the Periphery and in the Brain

In most mammals, OT is one of two peptide hormones (the other being vasopressin) that are secreted from the pituitary. Large neurosecretory cells (neurons modified to secrete peptide hormones into the blood) in the supraoptic (SON) and paraventricular (PVN) nuclei of the hypothalamus are major producers of OT, which they release into peripheral circulation via projections to the posterior pituitary (Wilkinson and Brown 2015). From there, OT circulates throughout the periphery, acting upon receptors located in a wide range of target tissues, including the gonads, uterus, mammary glands, heart, large and small intestines, and kidneys (Gimpl and Fahrenholz 2001; Fig. 1). The precise function of OT in many of these tissues has received scant attention, with the primary exceptions being the uterus and mammary glands. Cervical stretching and suckling induce pulsatile release of OT, which binds to receptors in uterine and mammary tissue and elicits contractions that facilitate parturition and milk ejection. These functions of the OT system

are highly conserved across mammalian species, including humans (Gimpl and Fahrenholz 2001).

In addition to functioning as a hormone in the periphery, OT regulates a variety of behaviors by acting as a neuropeptide signal in the central nervous system, comprised of the brain and spinal cord. Although the SON and PVN are the primary sites of OT production in the brain, other regions, including the hippocampus and septal area, also release OT in response to external stimuli (Landgraf and Neumann 2004). Furthermore, OT-containing neurons have been documented in extra-hypothalamic sites, including spinal cord and brainstem areas, as well as key nodes of the “social decision-making network,” a group of reciprocally interconnected brain nuclei that regulate multiple forms of social interaction, including parental, sexual, and aggressive behaviors (O’Connell and Hofmann 2011, 2012; Veening et al. 2015; Fig. 2). OT receptors are present throughout this network, though the distribution and abundance of receptors varies widely – often in conjunction with differences in social behavior – across seasons, species, and individuals (O’Connell and Hofmann 2012; Ondrasek 2016).

**Oxytocin, Fig. 1** Widespread distribution of OT receptors in the periphery of the rat, with purported or known functions included for each site. Both male and female sex

organs are shown (adapted with permission, Ondrasek 2016)

**Oxytocin, Fig. 2** Sites of OT production, as well as distribution and relative densities of the OT peptide, in the rat brain. OT-containing regions that are also components of the social decision-making network (SDM) are highlighted to emphasize extensive integration of the OT system throughout the network (SDM network nuclei were identified based on a neural network model proposed by O’Connell and Hofmann 2012). *Abbreviations:* AON anterior olfactory nucleus, BLA basolateral amygdala, BNST

bed nucleus of the stria terminalis, CA1 cornu ammonis 1 of the hippocampus, CC corpus callosum, CeA central nucleus of the amygdala, CoA/MeA cortical or medial amygdala, CPU caudoputamen, DEN dorsal endopiriform nucleus, DG dentate gyrus, ICj islands of Calleja, LS lateral septum, MPOA medial preoptic area, NAcc nucleus accumbens, OB olfactory bulb, PFC prefrontal cortex, PVN paraventricular nucleus, SON supraoptic nucleus, Thal thalamus (adapted with permission, Beery 2015)

Oxytocin’s action at receptors in both the brain and periphery is likely important for coordinating physiological and behavioral processes. For instance, during lactation, suckling stimulates the release of OT into peripheral circulation, which subsequently induces milk letdown; at the same time, OT is released in extra-hypothalamic areas, where it regulates the expression of maternal behavior (Landgraf and Neumann 2004). These complementary functions – the production of milk and expression of parental care – are both critical for the survival of young mammals. In light of such observations, it seems reasonable to predict that OT’s peripheral and central functions are integrated, and in some cases even synergistic. However, little is known regarding interactions between the peripheral and central divisions of the OT system, or, more generally, how OT actions in the brain are influenced by peripheral processes or stimuli (Goodson 2013; Landgraf and Neumann 2004).

### Structure and Function of the Oxytocin Receptor

Like the majority of peptide hormones, OT binds to a G-protein coupled receptor. Briefly, these receptors consist of a single folded polypeptide that is embedded in the cell membrane and composed of three major regions: an extracellular series of loops that engage in ligand binding; a transmembrane portion consisting of seven helical domains; and an intracellular portion that is bound to the G-protein, a trimer made up of three subunits. These receptors function by transducing an external signal (binding by a ligand) to the interior of the cell, where a subunit of the G-protein complex responds by dissociating and subsequently activating intracellular second messengers. These messengers activate protein kinases and the release of calcium ions, which, among other things, activate other chemical messengers and proteins that act as transcription factors (Wilkinson and Brown 2015).

In the brain, OT receptors have been identified not only at synapses but also on neuronal axons and glial cells (immune cells that support and protect the brain's neurons; Mitre et al. 2016). Oxytocin may reach these receptors through two broadly defined means – via classical synaptic transmission, where peptides are released into a synapse and facilitate localized, point-to-point communication, or via a more recently described process known as volume transmission, in which peptides are secreted into and diffuse throughout the surrounding extracellular fluid, allowing them to reach more distant target sites (Ludwig and Leng 2006). Several brain regions that are involved in mediating social behaviors express OT receptors but lack innervation by OT-containing neurons (such areas include the amygdala, ventromedial nucleus of the hypothalamus, and olfactory bulbs); these observations suggest that both synaptic and volume transmission are important for communication within the OT system (Landgraf and Neumann 2004; Ludwig and Leng 2006).

## **Oxytocin and Behavior (I): Social Behavior in a Reproductive Context**

The fundamental drive to reproduce underlies many social interactions, as individuals variously seek each other out to mate, cooperatively rear their young, or compete for access to resources critical for reproduction (e.g., food, territory, or mates). Oxytocin plays a key role in mediating a variety of reproductive social behaviors in mammals – that is, social interactions that directly impact the production or rearing of young (Anacker and Beery 2013). The influence of OT on specific types of reproductive social behaviors – namely, sexual behavior, maternal care, and pair bonding – are summarized below.

### **Sexual Behavior**

In 1992, it was suspected, but not yet known for certain, that OT regulates mammalian sexual behavior (Carter 1992). Today, a sizeable literature on rats (*Rattus norvegicus*), and more recently on humans, confirms that OT influences

multiple phases of male and female sexual behavior, including sexual excitement, orgasm and ejaculation, and sexual satiety (Veening et al. 2015).

In humans, peripheral OT increases in both sexes prior to copulation and following orgasm, although it is unclear whether this change in OT is a direct mediator or byproduct of sexual arousal and orgasm (Borrow and Cameron 2012). Nonetheless, the observed rise in OT prior to mating has led to the suggestion that this hormone prepares reproductive organs for subsequent sexual behaviors (Borrow and Cameron 2012; Veening et al. 2015). Multiple lines of evidence support this conclusion, including reports that OT receptors in epididymal and uterine tissues are linked to ejaculation and uterine contractions that occur during orgasm (Borrow and Cameron 2012). Furthermore, the PVN – one of the primary sites of OT production in the brain – receives sensory input from the genital regions in both sexes and contains OT-rich cells that project to spinal neurons involved in generating male genital reflexes (Normandin and Murphy 2011).

Additional evidence for OT's contributions to sexual behavior derive from reports that exogenous OT administration – that is, OT delivered either peripherally (e.g., intraperitoneally) or centrally (i.e., directly into the brain) – modify sexual interactions in males and females. For instance, in male rats, both peripheral and central OT treatments decrease ejaculation latency, time between mating bouts, and facilitate erections (Lee et al. 2010). Similarly, in female rats, central and peripheral OT treatments facilitate lordosis, a stereotyped posture (characterized by back arching, hind leg extension, and lifting of the head and rear) that females display during copulation, although this effect varies with environmental light cycles and the specific site of central infusion (Veening et al. 2015). Interestingly, despite the effects of exogenously administered OT on sexual behavior, male and female transgenic OT-knockout mice, which cannot produce OT, display a complete suite of sexual behaviors that yield successful impregnation. These findings raise important questions about the specific contributions of endogenous OT to the normal expression of sexual behavior (Lee et al. 2010).

### Maternal Care

By acting in both the periphery and brain, OT plays an evolutionarily conserved role in regulating several facets of maternalism, including lactation, parturition, and maternal behavior (Broad et al. 2006). Because they display strikingly different patterns of maternal behavior, rats and sheep (*Ovis aries*) serve as particularly important models for understanding OT's role in different aspects of maternal care. While female rats indiscriminately nurture any conspecific infant throughout the postpartum period, female sheep and other precocial mammals develop a highly selective preference for their own offspring; thus, rats have been used to investigate maternal attraction to offspring, while sheep have been used to examine the processes underlying selective maternal recognition (Numan and Young 2016).

In general, virgin female rats are averse to interacting with young and will only provide maternal care after an extended period of acclimation to pup stimuli, or if they are primed with hormones (Pedersen and Prange 1979). In the absence of such treatments, female rats giving birth to their first litters display full maternal behavior – characterized by grouping, licking, crouching over, and retrieving pups, as well as nest-building – in response to the hormonal changes that occur around parturition, including increased estrogen, decreased progesterone, and the release of OT into the brain (Numan and Young 2016). That OT plays an important role in mediating the onset of maternal behavior is underscored by reports that central infusions of OT and OT receptor antagonists promote and inhibit, respectively, the display of maternal care in female rats (Pedersen and Prange 1979; Pedersen et al. 1994). Critical to the expression of postpartum, maternal behavior is a neural circuit beginning with OT projections from the PVN to the medial preoptic area (MPOA), followed by subsequent projections to the ventral tegmental area and then to the nucleus accumbens (NAcc; Numan and Young 2016; Pedersen et al. 1994).

Like rats, female sheep will care for any infant immediately after parturition. However, maternal recognition and an enduring mother-offspring bond, concurrent with aggressive behavior

towards unrelated lambs, emerge within hours of birth. The onset of maternal selectivity involves the development of an olfactory preference for one's own offspring; OT's possible involvement in this process is supported by the finding that, during birth, OT is released into the brain's olfactory bulbs, which in turn project to other brain areas that mediate maternal behavior (Numan and Young 2016). In addition, central OT infusions promote maternal behavior and decreased aggression towards novel lambs in estrogen-primed ewes (Kendrick et al. 1987).

The above discussion of maternal behavior presents a convenient opportunity to briefly address the importance of interactions between OT and other neural systems. In the brain, OT operates within a complex milieu comprised of numerous compounds, including classical neurotransmitters (e.g., dopamine, serotonin, epinephrine, norepinephrine), steroid hormones (e.g., testosterone and estrogen), and other peptides (e.g., vasopressin). Although it is known that the OT system can both influence and be modulated by other neural systems, the behavioral consequences of such interactions are, in many cases, not as well understood as the actions of individual systems (Baskerville and Douglas 2008). Nonetheless, communication among these systems has important behavioral implications. For example, interactions between OT and dopamine – a neurotransmitter that plays a key role in coding the salience (either positive or negative) of social experiences and regulating reward-seeking behaviors – are important for establishing and maintaining maternal attraction to young after birth (Numan and Young 2016).

### Pair Bonding

The mother-infant relationship is a defining and evolutionarily conserved feature in mammalian taxa. In contrast, *pair bonds* – social bonds between unrelated, adult sexual partners who often share parenting responsibilities – are rare, occurring predominantly in the 5% of mammalian species that display monogamy. However, striking similarities between pair and mother-infant bonds exist; for instance, both types of relationships endure following prolonged periods of

separation. Similarities between these two types of social relationships, combined with the widespread incidence of maternal care across mammals, suggest that the mechanisms underlying maternal-infant bonds may have provided the neurobiological framework for the evolution of pair bonding (Numan and Young 2016; Williams et al. 1994).

A great deal of effort has been invested in elucidating the proximate causes of pair bonding, perhaps because monogamy often co-occurs with other intriguing social behaviors – including the assembly of family groups and altruism. Comparisons among closely related vole species (members of the Arvicoline subfamily of rodents) with different mating systems, either monogamy or polygamy, have been particularly revealing. These comparisons have relied heavily upon use of the partner preference test, a standardized approach for identifying pair bonds. In this experimental paradigm, a focal individual has the option of interacting with a stranger or a familiar conspecific (usually a cagemate or “partner”); individuals that spend significantly more time in contact with the familiar cagemate are said to have a *partner preference*, which is assumed to indicate the existence of a pair bond (Fig. 3; Numan and Young 2016).

In the monogamous prairie vole (*Microtus ochrogaster*), mating facilitates the formation of

pair bonds between males and females, although bonding can occur without mating following 24 h of cohabitation (Adkins-Regan 2009). Neuropharmacological studies demonstrate that OT influences the pair bonding process, whether bonds emerge following mating or simply cohabitation. In female prairie voles, brain infusions of OT promote bonding after a brief cohabitation of 6 h – a period normally too short for pair bonding to occur (Williams et al. 1994). Furthermore, infusions of an OT receptor antagonist inhibit the development of a partner preference in females after mating, indicating that OT also facilitates the effect of mating on pair bonding (Insel and Hulihan 1995). Such studies were thought to suggest that males and females rely on different peptide systems for the establishment of pair bonds; specifically, males and females were believed to be more sensitive to vasopressin and OT, respectively. However, more recent neuropharmacological studies in prairie voles challenge this view by showing that vasopressin modulates pair bonding in females, and conversely that OT receptor antagonists impede pair bonding in males (Young et al. 2008).

Elucidation of the neural circuits underlying pair bond formation emerged from neuroanatomical comparisons of peptide, receptor, and gene expression in monogamous versus promiscuous voles, such as the meadow (*Microtus*

**Oxytocin, Fig. 3** The partner preference test, a key experimental paradigm used to identify social bonds between familiar individuals, usually cagemates. The partner and a

novel individual are tethered in opposing forechambers, while the focal individual is placed in the rear chamber and allowed to investigate both stimulus animals freely

*pennsylvanicus*) and montane voles (*Microtus montanus*), which do not form pair bonds (Numan and Young 2016). For instance, in females the distribution and density of OT receptor and mRNA expression differ, such that they are higher in monogamous versus promiscuous species across several brain regions, including the NAcc and bed nucleus of the stria terminalis (BNST; Young et al. 2008). Particular importance of the NAcc in OT-mediated pair bonding in females is highlighted by a report that infusion of an OT receptor antagonist directly into the NAcc blocks mating-induced partner preferences in female prairie voles (Numan and Young 2016).

## **Oxytocin and Behavior (II): Nonreproductive Social Affiliations**

As described above, OT plays a critical role in mediating many of the physiological and behavioral processes that are key to successful reproduction. However, animals also interact in nonreproductive contexts, participating in relationships that do not immediately impact the production or rearing of young. For instance, individuals in numerous bird, fish, and mammalian species gather in large aggregations during the nonbreeding season; in addition, females in several mammalian species engage in long-term same-sex relationships that persist during nonreproductive periods. Such nonreproductive affiliations often occur in promiscuous species, underscoring the importance of recent efforts to revise the classical view that equates monogamy and polygamy with social and asocial behaviors, respectively (Anacker and Beery 2013; Goodson 2013).

Compared to OT's contributions to pair bonding and maternal behavior, far less is known about the peptide's role in regulating nonreproductive social behaviors, though recent discoveries address this disparity. Work involving species aside from the common rodent models – rats and mice – has revealed a great deal about OT's influence on behaviors that support group-living outside of the reproductive context. For instance, female meadow voles – which are

asocial during the breeding months, but group-living during winter – show variations in same-sex huddling behavior that are associated with OT receptor expression in the lateral septum (LS), such that receptor density in the LS declines as huddling time increases (Anacker and Beery 2013). This negative correlation between LS binding and huddling time mirrors interspecific differences between social and solitary species of rodents known as tuco-tucos. Specifically, colonial tuco-tucos show lower OT receptor expression in the LS than their solitary counterparts. Intriguingly, although female meadow voles show seasonal differences in OT receptor density in the NAcc – a region that is critical in pair bonding, as discussed previously – these differences are not associated with seasonal variations in same-sex social affiliation, nor is OT receptor expression in the NAcc correlated with huddling behavior, more generally (Beery and Zucker 2010). In combination, the above reports suggest that the neural circuits mediating group-living are distinct from those underlying pair bonding and implicate OT function in the LS as a mediator of rodent grouping behavior (Anacker and Beery 2013).

## **Oxytocin and Neuropsychiatric Disorders in Humans**

In humans, social relationships have a striking impact on physical and psychological wellbeing. Adults engaged in supportive relationships with their spouses, and children with secure attachments to their parents, have better long-term prospects – their overall sense of “happiness” is higher, and their health outcomes are improved relative to individuals without these types of relationships (Waldinger et al. 2015). Thus, efforts to uncover the neurobiological bases of human social behavior are of great value, not only for understanding inter-individual relationships but for identifying causes, and treatments, for human psychosocial disorders.

Studies of the OT system using rodents and nonhuman primates laid the foundation for similar investigations in humans. Efforts to elucidate

function of the OT system in humans have relied heavily upon two minimally invasive approaches: (1) assessment of the behavioral and cognitive consequences of intranasal administration of OT, and (2) identifying associations between behavioral phenotypes and polymorphisms in the genes encoding OT and/or its receptor. Polymorphisms in the OT receptor gene are associated with variations in several aspects of human social behavior and cognition, including empathy, facial recognition, separation anxiety, attachment phenotypes, and responsiveness to social exclusion (Johnson and Young 2017).

Reports such as those described above provide strong evidence that, as in other mammals, OT in humans plays an integral role in regulating social behavior. This conclusion prompted considerable excitement about the use of OT as a therapeutic for human neuropsychiatric disorders in which social dysregulation is a key issue, including autism spectrum disorders (ASD), schizophrenia, social anxiety disorder, and obsessive-compulsive disorder. Thus far, a case for OT's role in these conditions has been made most strongly for ASD. Promising findings include reports that polymorphisms in the OT receptor gene are associated with ASD across several different populations, and that OT treatment reduces repetitive behaviors and improves social communication in persons with ASD (Romano et al. 2016). However, it should be noted that interpretation of these outcomes has been met with some caution, in part because the mechanisms underlying the effects of intranasally administered OT remain unclear. Specifically, it is unknown whether intranasal OT can cross the blood brain barrier and thus gain direct access to socially relevant brain areas, although recent discoveries suggest that this is the case (Neumann et al. 2013). Furthermore, work in prairie voles demonstrates that while short-term administration of intranasal OT promotes social contact, chronic treatment inhibits social bonding (Bales et al. 2013); this finding raises concerns that treating neuropsychiatric disorders with repeated doses of intranasal OT may worsen, rather than improve, symptoms in the long term (Beery 2015; Romano et al. 2016).

## OT: More Than Just a “Pro-social” Hormone

After the early 1990s, the subsequent two decades of OT research focused heavily upon the peptide's pro-social effects, leading to its characterization as the “cuddle” hormone. However, recent discoveries involving multiple species reveal that OT promotes a spectrum of social behaviors, including not only affiliation but aggression, fear, and social exclusion. For instance, in prairie voles, OT not only facilitates affiliative interactions between mothers and pups, but aggression towards conspecifics; the latter is presumably a tactic for protecting young from infanticide. While OT receptors in the NAcc appear to promote pair bonding, elevated levels of the same receptor type in the LS have been associated with enhanced fear, decreased alloparental care, and reduced huddling behavior (Beery 2015). Furthermore, in humans, OT increases not only in-group favoritism and cooperation but racial biases and outgroup derogation as well. Such findings demonstrate that function of the OT system is highly context and circuit dependent and prompted Anacker and Beery (2013) to suggest that OT's mediation of both affiliative and agonistic behaviors, while seemingly contradictory, may actually help preserve group structure by establishing social order and maintaining stable group membership.

## Conclusion: Future Directions

Originally thought of as a “female” hormone that primarily regulates lactation and parturition, OT is now recognized as a versatile peptide with wide-reaching effects, not only on reproductive physiology but on numerous social behaviors (Anacker and Beery 2013; Beery 2015; Carter 1992). By 2015, OT studies numbered in the tens of thousands and revealed the diverse range of OT's neurobiological, endocrine, and behavioral functions; yet, many important questions regarding this peptide system still exist. For instance, much of what is currently known about the OT system derives from work conducted almost exclusively

in rodent and primate taxa, a bias that makes it difficult to determine how broadly conclusions about OT's role in the evolution of social behavior may be applied across mammalian species. Other unknowns include the OT system's sensitivity to environmental stimuli that impact social behavior (e.g., food availability), how or whether OT's functions in the periphery and the brain are integrated, and how the OT system mediates inter-individual variations in social phenotype (Ondrasek 2016). Given OT's likely role in social evolution and its promise as a therapeutic for human neuropsychiatric disorders, there is strong reason to predict that OT research will continue to grow and that many of these unknowns will be addressed in the coming years.

## Packet Theory

Kimberly Kirkpatrick  
Department of Psychological Sciences, Kansas  
State University, Manhattan, KS, USA

### Introduction

Packet theory (Kirkpatrick 2002; Kirkpatrick and Church 2003) was originally developed to provide a bridge between classical conditioning and interval timing. These two fields historically developed largely independently even though there is considerable overlap in the methods used to study the key phenomena in each field. Classical conditioning involves presenting a stimulus for a set duration, followed by an outcome that is usually biologically relevant. Initially, the stimulus evokes little or no response, but over the course of repeated pairings, conditioned responses (CRs) emerge and increase in strength. Although the stimulus is often presented for several seconds, CRs are usually measured collapsed over the whole period. Timing studies involve presenting a stimulus for a set duration followed by an outcome. Timing is typically studied within classical or instrumental conditioning paradigms, wherein the latter case a response is required to produce the outcome. Timing studies focus on the pattern of responses over the course of the stimulus. Both paradigms involve closely related procedures, and the primary difference is the

dependent variable for analysis (rate versus pattern of responding).

Prior to the creation of packet theory, Kirkpatrick and Church examined different theories of timing, conditioning, and some hybrid theories (Church and Kirkpatrick 2001). They reported that the hybrid theories performed best in accounting for both the rate and pattern of responding. Subsequently, it was found that appropriately timed responses were present at the earliest stage of learning (Kirkpatrick and Church 2000; Kirkpatrick and Balsam 2016), suggesting the need for a fully integrated hybrid model.

While these previous findings provided an important foundation, the most critical precursor to packet theory was the discovery of a general framework for determining the rate and pattern of CRs. Kirkpatrick and Church (2000) gave groups of rats a stimulus that lasted for different durations followed by food and with different times between foods or cycle times. They measured the head entries into the food cup (the CR) as a measure of anticipation of the upcoming food delivery. The response patterns over the whole cycle duration for the six groups are shown in the bottom panel of Fig. 1, with each function labeled with the stimulus/cycle durations. The shape of these functions reflects: (1) head entries following the previous food delivery to collect the food pellet, (2) an anticipatory gradually ramping response rate during the ITI, and (3) a sharper anticipatory ramping response rate during the stimulus.

**Packet Theory, Fig 1** (Top) A family of interval functions relating the mean stimulus or cycle duration to the mean response rate during the stimulus or cycle. (Middle) Arithmetic combination of the component functions to produce the predicted response rate gradients for each of the six groups. (Bottom) Actual response rate functions for each of the six groups (Adapted from Kirkpatrick and Church (2000))

The set of four groups with the 180 s cycle durations, but with stimulus durations of 15, 30, 60, or 120 s, shows that the ramping functions during the ITI are highly similar, but that the responding during the stimulus is determined by the stimulus duration, with shorter stimuli resulting in higher rates of responding and steeper increases. Comparisons of the set of three groups with 60 s stimulus durations, but with cycle durations of 90, 180, or 360 s, show that responding during the stimulus is similar, but the ITI responding differs. Using curve fitting to

determine a generating function for the response rates, Kirkpatrick and Church created a family of ramping functions for each of the different stimulus and cycle durations (Fig. 1, top panel). They then created combined functions (middle panel), in which the ITI response was determined by the function for the relevant cycle and the stimulus response was the arithmetic combination of the relevant cycle and stimulus functions. The linear combined functions are generally similar to the anticipatory response rate functions, minus the head entries at the very beginning of the interval.

## Packet Theory

Packet theory grew out of the linear curve fitting model of Kirkpatrick and Church (2000), but with some important extensions. Kirkpatrick and Church (2003) implemented different schedules of food deliveries (with no stimuli) in which the mean and variability of the cycle duration was manipulated across groups of rats using a fixed time (FT) schedule. They found that the mean cycle duration determined the mean rate of the response function, which mirrored the previous findings of Kirkpatrick and Church (2000). Moreover, the distribution of the cycle durations determined the pattern of responding. In addition, they reported that the head entry behavior occurred in response bouts or packets. The packets were invariant across different interval durations and distributions, but the pause times between packets were directly controlled by the cycle times. Thus, the packets of responding became the key unit of behavior that was predicted by packet theory.

The model is diagrammed in Fig. 2, with separate components for perception, memory, and decision. The perceptual module of Packet theory consists of ramping functions associated with individual intervals. In an FT 90 s, the ramping functions would all be the same and would span the 90 s duration, but for random (RT) or combined FT–RT functions, the ramping functions would vary across cycles according to the distribution of intervals. The memory module in packet theory is a weighted sum of the individual ramping functions from the perceptual module, with the weights determined by the free parameter

**Packet Theory, Fig 2** The perception, memory, and decision components that comprise packet theory, with application to fixed time (FT), random time (RT), and combined FT–RT schedules. The perception module consists of linear ramping functions ( $e_t$ ) that are determined by the experienced intervals. Each ramping function is determined as a function time ( $t$ ) and spread across the duration ( $d$ ) of the interval. The conditional expected time function

in memory ( $E_t$ ) is a weighted combination of the individual ramping functions ( $e_t$ ), with the effect of relatively recent intervals determined by the weighting parameter,  $\alpha$ . The decision module issues packets of responses, with the probability of packet generation ( $p_t$ ) determined by a transposed conditional expected timing function from memory ( $E_t^*$ ) multiplied by a responsiveness parameter,  $n$  (Adapted from Kirkpatrick and Church (2003))

$\alpha$ . This is a conditional expected time function, which is the expected time until food, given that food has not yet been delivered. The decision module determines the probability of packet occurrence, which is inversely related to the conditional expected time function in memory. The packets of responding contain a random number of responses with random interresponse times. The functions for generating the model packets were determined by fitting functions to the packets generated by the rats. The number of packets per interval,  $n$ , is the second free parameter in the model, which determines overall response rates regardless of interval duration.

Kirkpatrick (2002) demonstrated several applications of packet theory in the timing and conditioning domains, showing quantitatively correct predictions of the following phenomena. (1) The scalar property, a key feature of interval timing (Gibbon 1977). (2) The rate of CRs during the

stimulus across a range of stimulus durations, a measure of the strength of conditioned responding. (3) The rate of CRs during the ITI across a range of cycle durations, a potential measure of contextual conditioning. (4) The rate of CRs during the trace interval, when there is a gap between the stimulus and outcome. (5) The effect of stimulus: cycle duration (Gallistel and Gibbon 2000) on the relative rate of CRs during the stimulus. Packet theory also makes a novel prediction that organisms time all distributions of durations, which does appear to be the case, at least in rats (Kirkpatrick and Church 2003). Timing of exponential random intervals occurs because the conditional expected time is flat and thus the model predicts randomly distributed packets of responding. Thus, timing of fixed and random intervals is accomplished with a single process rather than assuming that organisms time fixed intervals, but do something different with variable intervals.

## Evaluation and Extensions of Packet Theory

Compared to many timing and conditioning models, packet theory has a benefit of being relatively inflexible and parsimonious. The perceptual and memory components are driven by the stimulus inputs, with the only free parameter being the memory weighting parameter which affects the relative influence of recent events. The response output is driven by the memory component, but with an added response rate parameter. The packets are determined by the properties of previous data. Yet, despite these constraints, the model offers unique and accurate predictions of response rate and pattern in basic interval schedules that bridges the fields of classical conditioning and timing. However, all models have weaknesses, and one major weakness of the original version of packet theory is that it did not include a mechanism for learning nor did the model include any mechanism for the occurrence of extinction when outcomes are withheld. This is a serious challenge of the model for application to many classical conditioning phenomena.

More recently, Guilhardi et al. (2007) developed an extension of packet theory, known as the modular theory, designed to build on the strengths of the original model but also overcome the major weaknesses. The most noteworthy change in the modular theory is the separation of the memory into two components: pattern and strength memories. The pattern memory closely resembles the original packet theory memory function and is only influenced by reinforcement. A new strength memory component was added, based on the Rescorla–Wagner model (Rescorla and Wagner 1972), in which the associative strength of the stimulus is increased or decreased dependent on outcome delivery or omission, respectively. This change allowed the modular theory to explain basic acquisition and extinction phenomena. Most importantly, because pattern memory is only updated when reinforcement occurs, the response pattern and the maintenance of associations are maintained during extinction, consistent with several findings in the literature (Guilhardi and Church 2006). However, these improvements in the model were

accompanied by an increase in complexity and flexibility of the model, thus losing some of the original strengths of packet theory, although it is possible that the model implementation could be simplified for some applications by fixing a subset of the free parameters.

## Conclusion

Packet theory and the modular theory are attempts at building models that bridge classical conditioning and timing. This is an important venture that can spark new research, and new model development should continue in this area. In addition, more research is needed at the intersection of these two fields to provide unique data to guide and constrain future model development.

## Definition

Responsible regard and treatment of nonhuman animals based in part upon their capacity to experience pain and manifest some form of sentience.

## Introduction

Neuroscientific assessment and definitions of mechanisms of sensation, cognition, emotion, and behavior have engendered a view of neural systems – and their functions – as embodied within organisms-in-environments. Understanding the neural bases of organisms’ ecological interactions has two-fold value: first, it fosters insight to the neurocognitive capabilities of individual beings and various species; and second, it prompts deeper reflection and more thorough address of what such functions and capacities *mean* relative to the ways that organisms are regarded and treated. As history reveals, the use of even simple forms of neurocentric criteria to shape categorical distinctions of what types of organisms, and which individuals may claim particular social goods is not new (Aristotle 1966). The scope and pace of contemporary neuroscientific advancement(s) has only fortified this trend, in part through heuristics that have been influential to establishing theories of mind. But, a theory of mind is a powerful tool, and with this power comes considerable responsibility (Giordano 2010; Giordano and Benedikter 2012; Giordano et al. 2012).

Much of the information gained from neuroscientific research has been derived from animal models. Increasingly, scientific evidence confirms that many animal species (e.g., mammals, several species of vertebrates, cephalopods, certain insects) have nervous systems of sufficient structural and functional sophistication to sustain complex cognitive processes. This challenges long held beliefs about animals’ capacity for experiencing consciousness, pain, and emotions, and contests rather dogmatic philosophical distinctions between humans and animals (Griffin 1994; White 2007).

A deepening understanding of the ways that nervous systems and brains are involved in (or evoke) those characteristics—valued within individuals, groups, and a species—should compel and sustain the ways that the organisms possessing such characteristics are regarded and treated. But, it is not clear whether humanity will be willing and able to embrace such knowledge to revise the moral attitudes and the ethics and policies affecting nonhuman animals. The relatively new field of neuroethics may be useful to address these challenges in that it grounds the discipline and its practices to: (1) a naturalistic philosophy; (2) the current epistemological capital of neuroscience; (3) the moral issues, problems, and solutions arising in and from neuroscientific research and its applications; and (4) a neurocentric criteria to define and resolve ethical questions and decisions (Giordano 2011, 2012; Giordano et al. 2012).

### **Painience as a Fundamental Neuroethical Criterion**

The recognition of sentience as a basis for establishment of ethical and legal codes for animals represents an explicit departure from arbitrary speciesism, and a noteworthy advancement toward the employment of neurocentric criteria. However, there is still much that remains unknown about the neurocognitive function(s) of animals, which tends to complicate determinations of what species of animals are sentient, the nature of such sentience (e.g., shifting definitions of “higher” and “lower” consciousness), and if and what particular properties of sentience should be relevant. This makes it difficult to discern the extent of moral regard and level of good that should be afforded (i.e., ranging from what might be considered obligatory to that which is supererogatory).

An organism’s capacity to feel pain as noxious (injurious) and explicitly hurtful (viz., pain *qua* pain; not simply nociception, but noci-perception) represents a minimum criterion upon which to base and predicate moral consideration and actions (Bentham 1823; Giordano 2009, 2010). But this too, is not without complication. The formal definition of pain as “...an unpleasant

sensory and emotional experience...” (IASP 2009) obtains that for an objective neural event to be subjectively experienced as pain (and not merely a high intensity, aversive stimulus), it would necessarily involve the combinatory qualities of sensation, cognition, and emotion. To be sure, pain is a multidimensional event that involves and is derived from “...a sensation in a part of the body...and an emotional experience...” (IASP 2009).

Some have claimed that animal pain is not as significant as that of humans, given that certain areas of the cortex and neural pathways that have been shown to be responsible (in humans) for the associative linking of sensations to cognition and emotion are not present in all animals (IASP 2010). These assertions are objectionable on several grounds. First, these positions fail to acknowledge the most current perspective(s) regarding the structure–function relationship of nervous systems; these can be colloquially summarized using a computer analogy to posit that the presence of the “wetware” (i.e., the neural substrates) is often a reliable predictor that the “program” (e.g., pain) can and will be executed. This is strengthened by comparative studies of mammalian species as anatomical, physiological, and behavioral models of human development, neurophysiology, and pain (Bekoff 1995). Perhaps what is more important is the recognition that the experience of pain, while involving a number of higher neuroanatomical loci (e.g., the somatosensory and associative cortices), is also reliant upon subcortical structures. These structures likely do not function site-specifically, but are engaged as and within hierarchical networks, the properties of which contribute to mental process(es) (Baars 1998; Edelman 2004).

Thus, the second flaw in arguments that attempt to negate the experience and profundity of animal pain is that they tend to attribute the function of networked hierarchies of neural structures (if not the whole brain) to particular parts (i.e., what has been called the “divisional” or mereological fallacy) (Bennett and Hacker 2003).

Third, is that 1-to-1 representation of neural structure–functional relationships between humans and animals need not be present for the

occurrence of cognitive, emotional, and behavioral processes. The networks involved in pain processing are not necessarily identical (i.e., homologous) to those of humans, but instead may – and often do – function analogously to conjoin distinct neural substrates to obtain the pain event and experience. This speaks in return to the second point – namely, that brains are embodied within an organism and this individual neural structure and function gives rise to differing subjective experiences.

At present, we cannot know the phenomenological characteristics of animal pain; and while an understanding of organisms' nervous systems' capacity to subtend pain is necessary and important, argument-by-analogy supports the use of behavioral expressions of pain such as increased vocalizations, agitation, writhing, reluctance to move and decreased locomotion, attending to and guarding parts of the body, and huddled postures. In mammals, such behaviors have been shown to represent more than merely “pseudo-affective” responses, and are now regarded as manifestations of cognitive and emotional processes, and abstract dimensions of fear, and (some form of) suffering (Sufka et al. 2009).

Such types of attending, guarding, and writhing responses have also been identified in crustaceans, and certain insects and other invertebrates. Additionally, it has been shown that these creatures have nocisponsive nerve endings, specialized nociceptors, and defined neural pathways to subserve high intensity noxious stimuli. Taken together, these findings would allow the possibility that such organisms experience at least nociception, and some type of noci-perception may also be plausible. Therefore, recognition of the neuroscientific fact that pain *can* occur in a particular organism is a necessary and sufficient condition to afford that organism moral consideration and respectful treatment. This is not inconsistent with a number of ethical traditions that base human action upon premises of non-harm and/or some version of a “golden rule” maxim (i.e., “do unto others”) that begins from a presumption that said others can experience “hurt” as similar or analogously to the way(s) that humans know it. To take this argument a step

further, the obligation to exercise this modicum of consideration and care reflects, and is derived from, the existential vulnerability of painient non-human animals that positions them as the subjects of human responsibility and care.

### Ryder's Painism Reconsidered

In this context, Richard Ryder's thesis of “painism” offers a number of precepts (i.e., what Ryder called “rules”) for the prevention and treatment of pain that may be worthwhile to a neuroethical approach to the moral regard and treatment of animals (Ryder 2001). Ryder's core thesis defines the nature and purpose of morality and ethics as relative and relevant to pain and the painient. The imperative to recognize animals' capacity to experience pain, and the human responsibilities that arise thereupon are obtained in the claim that “...*moral standards should apply equally to all painient individuals, regardless of species*” (Ryder 2001).

From these fundamental premises follow prescriptions against the infliction of “*unconsented pain*,” and pain “...*for trivial purposes*” (Ryder 2001). These assert responsibility for the stewardship of contemporary knowledge of neural mechanisms of animal pain and the power to inflict, prevent, and/or mitigate pain, which should undergird the ethical treatment of animals, in general. Explicit to these statements is the importance of a more finely grained analysis of the ways that animal welfare is imparted in other utilitarian agendas of human society.

### Painience and Precautionary Conduct

This argument may stand as a basis for both individual reflection and to contribute to guidelines and policies for the treatment of animals. This aim does not deny human needs and motives for flourishing. Nor is this a call for strict veganism, the abandonment of all animal products, and divorce from keeping pets, zoos, and the use of service and work animals. This is not an exhortation of extremism in the moral consideration and treatment of animals. But, it is important to use the most current evidence from neuroscience to inform epistemology, the generation of useful neurocentric criteria in the formulation of

ontologies, and the regard for both human and nonhuman beings. Simply put, recognition of pain in nonhuman animals dictates human responsibilities to minimize or prevent the infliction of pain in these creatures.

### Pain Research Involving Animals

But it is in this spirit of inquiry that yet another potential conundrum is encountered: Given that research is the principal tool that enables the articulation of science and acquisition of knowledge, there is a rational and defensible argument for continued studies to further elucidate the neurocognitive functions and capabilities of animals. Yet, the goals of such investigations, how such studies are undertaken, and how findings are utilized are equally important if science is to remain ethically sound. Pain research involving animals provokes particular ethical discussion and controversy, since it axiomatically is intended to elicit pain in the research subject, and a full presentation of this discussion exceeds the limits of this entry (see, for example, the work of Greek and Greek 2010; and Regan 2001).

To reiterate, while the phenomenology of pain cannot be objectively measured in animals (including the human animal) (Giordano et al. 2010), behavioral and physical responses to painful stimuli can lead to strong inference(s) regarding accompanying and resultant unpleasant emotional experience. So, while it is possible, and in some cases likely, that the perception and meaning of animal pain is different from that of humans (given distinctions in ecology, lived body, and life world), it is important to acknowledge that neural systems are in place and operational that allow many animal species to experience such stimuli as “noxious,” and this noxiousness is fundamental to the cognitive-emotional event, and hurtful nature of pain.

Animal studies have been important to guide and complement investigations involving human subjects (Mogil et al. 2010). However, a number of limitations and criticisms of animal models of pain have been brought to the fore, including a lack of ecological validity, narrow emphasis upon sensory events, lack of correlation to clinical pain

states in humans, inadequacies when addressing the epidemiology of chronic pain (in both human and animal populations), and inferiority of design and reporting standards (Mogil et al. 2010; Herrmann and Jayne 2019).

Identifying these gaps and inadequacies is crucial to the iterative reappraisal of the scope, conduct, and value of pain research in animals (if not animal research, overall). Questions essential to such reappraisal reflect the well-known “Three R’s” (reduction, revision, replacement), as proposed by Russell and Burch, and pose: (1) whether painful methods can be replaced with other, less invasive protocols; (2) if and how protocols and methods can be refined to minimize the painful nature of the research; and (3) whether and how the numbers of animals – and perhaps overall number of studies – can and should be reduced (Russell and Burch 1959).

There is continued uncertainty and debate within the scientific community as to whether animals provide a realistic model of human pain (Bennett and Xie 1988; Mogil 2009; Herrmann and Jayne 2019). This reflects a type of “extrapolation dilemma” (Steel 2007), which elicits two potential scenarios that are important to the ways that results from research studies are used. In *Scenario A*: the model is “distant” and therefore, while providing some information, remains “insufficient” for direct comparative applications due to differences and gaps in the structures and functions of systems studied. The *Resulting Implication*: is to abandon the model in favor of others that are more proximate and applicable. In *Scenario B*: the model is “proximate” and therefore “sufficient” given the similarity of structures and functions of those systems studied to the comparative target. The *Resulting Implication* is that information from the model should be applied both to the comparative target *and* to the model. If it is (rightly) assumed that current animal models of pain fulfill criteria of being proximate and sufficient sources for information that may be directly relevant, and translate to knowledge about human systems, then what is learned from studying animals – to gain information about humans – is applicable to both humans, *and*

those animals (i.e., the species) that are the object of study. If this is so, then the good of research could be maximized through the application and use of such knowledge to inform and direct subsequent actions toward both humans *and* animals.

From this, a foundational stance for the conduct of animal research and care could be derived from, and based upon a version of Rawls’ principle of *maximin*: Given (a) the unequal distribution of knowledge, capability, and power between humans and animals, and (b) reasonable expectation that any organism with the anatomical and physiologic capabilities for pain will manifest this experience, then (c) ethical probity can be achieved and sustained by maximum prevention and mitigation of such pain, as a minimum benefit that should be allocated by those in power toward the provision of the welfare of those organisms over whom such power is exercised (Rawls 1971).

Conclusion

It is important to recognize the potential benefit of animal pain research to both human and veterinary medicine, but it is equally important to question how, and to what effect research findings will be utilized. In light of knowledge about pain gained from such investigations to date, continued pain research in animals is acceptable if and only if any and all such studies: (1) adhere to practical and ethical guidelines that are consistent with the most contemporary understanding of comparative and cognitive neuroscience, (2) adopt a frank precautionary stance when the welfare of any painient creature is at risk, and (3) attempt to directly employ research findings to benefit animal species (i.e., reciprocal and/or reverse translation), writ both small (i.e., within veterinary practice) and large (i.e., as applied to the care and treatment of wild, captive, livestock, and domestic animals). Toward such ends, an expansion of the 3 Rs may be useful (i.e., 3 Rs + 3) to include broader precepts that are applicable both to research and more general regard and treatment of animals, see Table 1.

**Pain and Ethics of Animal Care and Use,**  
**Table 1** 3Rs + 3 Precepts and Practices

|                                                                                                                                                                   |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Reflective and Precautionary Process                                                                                                                              |
| 3 Rs + 3:                                                                                                                                                         |
| <b>Respect:</b> For knowledge to date, as well as the animal subjects (of research) and animals in general,                                                       |
| <b>Reciprocal Translation:</b> Of animal research toward human trials to veterinary and animal welfare applications when/where appropriate,                       |
| <b>Responsibility:</b> To appreciate and use the most current information about animal painience and cognition to guide regard and treatment of nonhuman species. |

Although painience may be a minimum criterion for neuroethical regard, this is but a first step, as further understanding of animal consciousness, emotions, and higher cognitive functions should instantiate stricter moral standards for animal research and welfare. As shown in Table 1, these neuroethical premises are not merely confined to the laboratory, but extend into the public sphere to affect social conduct, as well.

An important element in the social acknowledgment and embrace of new concepts will be the development of neuroethically informed and neuroethically based programs of primary, secondary, and post-secondary education. Such programs would inculcate more meaningful apprehension of the ways that neuroscience may foster a nonanthropocentric appreciation of animals, and strengthen the notion of human/animal differences as distinctions of degree, rather than natural kind, and in so doing weaken anachronistic dualisms that have guided human treatment of animals. This will be evermore necessary as (1) society becomes more neuroscientifically and technologically capable, dependent, and oriented; (2) neuroscience and technology become increasingly powerful forces of social construction and/or deconstruction; and (3) humanity confronts the growing, incumbent responsibility to use such knowledge and technology in ways that are morally sound.

In conclusion, the aim is not to prescribe a form of neuroethical absolutism, for individuals’ moral compasses differ, and cultural norms and mores vary. But any ethical analysis must begin from

fact(s), and it is hoped that neuroscientific information about the cognitive capabilities of other species will dispel dated apologia for the mistreatment of animals, and foster a sense of awareness and responsibility to inform and guide the ethical reflections, choices, and actions of both individuals and societies.

## Pair Bond

Brett M. Frye  
Department of Biological Sciences,  
Clemson University, Clemson, SC, USA

### Definition

A selective and enduring relationship between two unrelated adults that can be characterized by affiliative interactions, spatial proximity, distress to separation, aggression toward unfamiliar individuals, and/or sexual fidelity.

### Introduction

Animals from a broad array of taxa, ranging from parakeets to humans, form stable, lasting associations known as pair bonds. While pair bonds have been observed across the animal kingdom, most information about this phenomenon originates from studies of voles, birds, and primates. These taxa have provided key insights about the mechanisms responsible for the formation and maintenance of pair bonds. Additionally, this research has been critical for understanding the ecological and evolutionary processes associated with pair bonds.

### Social Versus Sexual Pair Bonds

Animals that form pair bonds interact socially as well as sexually. However, sexual exclusivity is quite rare for many species (Lukas and Clutton-Brock 2013). Researchers sometimes fail to specify which component of pair bonds, social or sexual, is being investigated. Imprecise terminology creates challenges for comparisons of pair bonding in different species. Such ambiguity also impedes comparisons across disciplines (e.g., psychology, ecology, and medicine). As such, studies of pair bonding should specify whether the relationships of interest are social or sexual (or both) (Fuentes 2002). These

clarifications will bolster efforts to understand the ecological and evolutionary implications of pair bonds.

### Evolutionary and Functional Origins of Pair Bonding

Several hypotheses aim to explain the evolutionary origins and adaptive significance of pair bonds. These proposals share a unifying supposition – pair bonds likely originated from a sustained male-female association following mating. Mechanisms strengthening these relationships might have been favored if stable, lasting partnerships conferred adaptive (i.e., survival and reproductive) advantages over unstable or ephemeral associations. Several of these hypotheses are outlined below:

*Infanticide prevention* (van Schaik and Dunbar 1990). Pair bonds may have evolved as a means to mitigate the threat of infanticide. In systems where males regularly kill unfamiliar infants, pairs may have been able to protect offspring better than single parents. If bonded individuals experienced reductions in offspring mortality, pair bonding could have evolved as an adaptive strategy to maximize reproductive success within these populations.

*Mate guarding* (Parker 1974). Males that maintained close spatial proximity to females may have monopolized matings by forestalling females' reproductive attempts with other individuals. Additionally, ecological contexts may have constrained males' abilities to locate additional females. If so, males that stayed close and guarded females may have produced more offspring than males that departed after mating.

*Females as limited resource* (Wrangham 1980). Pair bonding may have evolved because ecological conditions limited males' abilities to secure a home range productive enough to support multiple females. What is more, constrained dispersal may have generated a situation in which males that maintained close associations with females produced more offspring than males that roved across territories.

*Parental care* (Kleiman 1977). Pair bonding may have evolved because biparental care (e.g., provisioning, carrying, huddling, thermoregulation, or grooming) was critical for the survival of offspring. Additionally, closely bonded individuals might have provided superior care, thereby promoting the survival of their offspring.

## Neuroendocrinology of Pair Bonding

Behavior and physiology are inextricably linked. The neuroendocrinology, i.e., the neural and hormonal mechanisms, of pair bonding has been most thoroughly described for a single species – the prairie vole (*Microtus ochrogaster*) (Aragona and Wang 2004). Prairie voles are small, territorial rodents that often form monogamous social bonds for life. Prairie vole partnerships are characterized by clear social preferences for mates, selective aggression toward conspecifics (i.e., members of the same species), and biparental care of offspring (Aragona and Wang 2004). These traits, in addition to high fecundity and amenability to captivity, make prairie voles excellent models in which to investigate the causal mechanisms of social attachment and pair bonding.

Research with prairie voles has uncovered several hormones that are fundamental for pair bonds. These include oxytocin (OT), arginine vasopressin (AVP), dopamine (DA), and corticotropin releasing hormone (CRH) (Aragona and Wang 2004; French et al. 2017). These hormones work in concert to regulate pair bonding and promote the maintenance of bonds once they have formed. However, the action of these hormones is not uniform across the sexes. The binding of OT is critical for pair bonding in female voles, whereas AVP is essential for males. Differences in the distribution and density of hormone receptors, rather than levels of the hormones themselves, best explain this sexual dimorphism (Aragona and Wang 2004).

Evidence from other species, including some birds and primates, suggests that OT, AVP, DA, and CRH are important regulators of pair bonding (Klatt and Goodson 2012; French et al. 2017). For

example, approximately 60% of neotropical monkeys exhibit behaviors characteristic of social monogamy and pair bonding, whereas only 29% of all primates are socially monogamous (Lukas and Clutton-Brock 2013). Preliminary evidence from several species (i.e., titi monkeys, marmosets, macaques, and humans) suggests that differences in the OT and AVP systems may explain these differences in the behaviors associated with pair bonding (French et al. 2017). In birds, hormones related to OT and AVP also influence pair bonding behaviors. For example, inhibiting vasotocin (VT), the compound from which OT and AVP are thought to have evolved, hinders pair bonds in zebra finches (*Taeniopygia guttata*). Finches with blocked VT receptors take longer to form bonds and have more unstable bonds than do finches with functional VT receptors (Klatt and Goodson 2012).

## Development and Pair Bonds

Early experiences can have lasting consequences for behavior. For many species, the quality and quantity of parental care can have lifelong impacts on social repertoires. In prairie voles, parents that provide high levels of care raise offspring that are typically more affiliative than offspring whose parents provided less care (Arias del Razo and Bales 2016). These sustained differences were evident when young voles matured and formed pair bonds themselves. Voles that had received high levels of care as infants spent more time in contact with their mates than did voles that had received low levels of care (Arias del Razo and Bales 2016). This suggests that attributes of pair bonds may have consequences that extend across generations.

## Conclusion

Pair bonds are complex and curious. They stimulate a wide range of questions, including: Why should animals prefer one, rather than many, social partners? What ecological and social pressures favor the evolution of selective relationships? Why do some animals pair for life whereas others

separate after one breeding season? What are the neurobiological mechanisms modulating prolonged associations? How do pair bonds develop? What shapes an individual's propensity to bond with others? These questions have been addressed only for a few species. As such, studies from across the animal kingdom are needed to acquire a comprehensive understanding of this phenomenon. What is more, inputs from myriad disciplines, including social psychology, evolutionary biology, ecology, and anthropology, will ultimately strengthen explanations of the proximate and ultimate mechanisms underlying pair bonds.

## Introduction

Richard Owen coined the term Dinosauria in 1841. Ever since, paleontologists and laypeople alike have been fascinated by these extinct creatures. In the past three decades, the number of academic publications on Dinosauria has increased considerably, providing the scientific community with a better understanding of life in the Mesozoic. Moreover, current studies have moved beyond anatomical and geological descriptions toward a clearer portrayal of various

behavioral, physiological, and neuroanatomical traits. In addition to discussing recently altered classifications in phylogeny and cladistics, this encyclopedia entry will describe the implications of multiple paleobiological studies on describing growth, reproduction, parental behavior, sociality, and ecology in Dinosauria. The entry will also briefly mention the various extinctions, both major and minor, that occurred during the Mesozoic. While the evolutionary repercussions of the Cretaceous–Paleogene event are indisputable, other extinctions generated similarly vast ecological shifts. For instance, the rise of Dinosauria itself is due in part to the Late Triassic mass extinction that vacated numerous ecological niches. Consequently, this entry's final section will address several factors that led to the dramatic elimination of hundreds of species during different periods of the Mesozoic.

## Cladistics and Evolution

Archosauria evolved as a clade around 250 million years ago, after the Permian–Triassic extinction which eliminated over 90% of all species on Earth (Brusatte 2012). This ecological catastrophe vacated numerous ecological niches, enabling the rapid spread and diversification of species. Most archosaurian lineages emerged toward the end of the Early Triassic (Brusatte 2012). Paleontologists classify Archosauria into two main subclades, Crurotarsi and Avemetatarsalia (also known as Ornithodira). Crurotarsi encompasses lineages such as Phytosauria, Crocodylomorpha, Rauisuchia, and Aetosauria. Alternatively, researchers generally divide Avemetatarsalia into Pterosauria (flying reptiles), Dinosauriomorpha (small-sized archosaurs including *Silesaurus*, *Asilisaurus*, *Marasuchus*, and *Lagerpeton*), and Dinosauria. Traditionally, Dinosauria is classified into two main subclades: Saurischia and Ornithischia (Brusatte 2012).

### Saurischia

Akin to other Dinosauria clades, Theropoda evolved during the Late Triassic as small- (*Eoraptor*) or

medium-sized (*Herrerasaurus*) animals. Hence, in contrast to their descendants, theropod species in the Triassic faced a constant struggle with larger competitors such as Rauisuchidae (*Postosuchus*, *Polonosuchus*) and Prestosuchidae (*Prestosuchus*, *Saurosuchus*) archosaurs, wherein it was not uncommon for early theropods to fall prey to these massive quadrupedal predators. It was only with the extinction of rauisuchids and prestosuchids (among others) and the subsequent release of previously occupied ecological niches at the end of the Triassic that this clade diversified, leading to the rise of large-bodied predators in the Jurassic and the Cretaceous. Theropoda is subclassified into three major groups, Neotheropoda, Tetanurae, and Coelurosauria (this last one is usually described as a branching node emerging from Avetheropoda within Tetanurae). The first clade includes families such as Coelophysidae (*Coelophysis*), Dilophosauridae (*Dilophosaurus*), Noasauridae (*Noasaurus*), and Abelisauridae (*Abelisaurus*). In turn, Tetanurae contains, among other groups, the families Megalosauridae, Spinosauridae, Allosauridae, Carcharodontosauridae, and Neovenatoridae. Lastly, the derived group of Coelurosauria includes tyrannosauroids, compsognathids, ornithomimosaurs, alvarezsauroids, therizinosauroids, oviraptorosaurs, scansoriopterygids, deinonychosaurs, and Paraves.

Phylogenetic reconstructions have traced Sauropodomorpha's evolution to the Late Triassic, with prosauropod species such as *Massospondylus*, *Plateosaurus*, *Riojasaurus*, and *Lufengosaurus* (Brusatte 2012). Additionally, although paleontologists originally described Prosauropoda as a distinct clade, contemporary phylogenetic classifications no longer support this position. Comparative morphological analyses indicate that this "lineage" encompasses various sauropodomorph taxa featuring sufficient morphological differences to be considered a unified clade (Brusatte 2012). The persistence of basal sauropodomorph traits in early sauropods further calls this claim into question (Brusatte 2012). Beyond these caveats, the term prosauropod remains in use due to the observable variation between these Late Triassic species, with more

derived sauropod taxa generally found in Late Jurassic geological formations.

Sauropodomorph diversity increased substantially during the Jurassic. Mamechisauridae taxa, including *Mamenchisaurus* and *Omeisaurus*, evolved between the Middle and Late Jurassic in Asia. The derived clade of Neosauropoda contained two main subclades: Diplodocoidea and Macronaria. Concerning Diplodocoidea, three main families comprise this superfamily: Rebbachisauridae, Dicraeosauridae, and Diplodocidae. Of these three families, the Rebbachisauridae taxa (e.g., *Nigersaurus* and *Rebbachisaurus*) are the most basal clade, whereas Dicraeosauridae and Diplodocidae are generally viewed as more derived lineages. Dicraeosaurids are characterized by elongated neural spines, as observed in *Amargasaurus* and *Dicraeosaurus*. The Diplodocidae family covers large-bodied sauropod species commonly found in Late Jurassic North America. Well-described taxa include *Diplodocus* and *Apatosaurus*. Concerning Macronaria, this clade contains the tallest and heaviest sauropod taxa. *Argentinosaurus* and *Paralititan*, part of the subclade Titanosauria, are among the largest animals observed in earth's evolutionary history. Brachiosauridae (*Brachiosaurus*, *Sauroposeidon*) and Camarasauridae (*Camarasaurus*) are other macronarian families of the Jurassic, with the former clade found in Gondwana and Laurasia and the latter endemic to Laurasia.

### Ornithischia

The clade of Ornithischia is divided into two major groups, basal species and Genasauria. Basal taxa emerged as small-sized bipeds in the Early Jurassic that generally occupied either an herbivorous or omnivorous dietary niche (Heterodontosauridae: *Fruitadens*, *Heterodontosaurus*). Alternatively, Genasauria includes more derived clades such as Thyreophora and Cerapoda. With regard to the former, thyreophorans usually exhibit bony armor, such as osteoderms, plates, spikes, or clubs. Modern phylogenetic reconstructions suggest this clade evolved during the Early Jurassic, with some

small-bodied species such as *Scutellosaurus* and *Scelidosaurus* (a potential out-group species) displaying some morphological commonalities with the more derived thyreophorans (Brusatte 2012). Thyreophora is subdivided into Stegosauria (e.g., *Kentrosaurus*, *Dacentrurus*, and *Stegosaurus*) and Ankylosauria (*Ankylosaurus*, *Euoplocephalus*, *Nodosaurus*, and *Edmontonia*). Unfortunately, to this day, there is little agreement regarding the phylogeny of Stegosauria, with multiple phylogenetic trees providing different classifications. In contrast, paleontologists tend to agree on the phylogenetic structure of Ankylosauria, a clade divided into Nodosauridae (characterized by bony ornamentations above the eyes and around the snout; Brusatte 2012) and Ankylosauridae (featuring a club at the end of the tail and heavily armored craniums; Brusatte 2012).

Concerning Cerapoda, this clade branches into Marginocephalia and Ornithopoda. Marginocephals usually display either a bonny frill or skull dome (comparative anatomical analyses indicate these structures originate from parietal and squamosal regions). While domes are a common feature of Pachycephalosauria (e.g., *Pachycephalosaurus* and *Stegoceras*), frills and horns are frequently observed in the clade Ceratopsia. Paleontologists attribute the evolution of domes, frills, and horns in Marginocephalia to either natural (marginocephals may have used these osteological structures as antipredator defense) or sexual selective (as armaments during intrasexual contests or as ornaments aimed to attract the attention of a female) pressures. Akin to other Dinosauria, ceratopsians evolved as small-bodied animals (*Psittacosaurus*). Eventually, ceratopsians increased in diversity during the Early Cretaceous, with the emergence of several families in North America, Europe, and Asia (basal lineages such as Protoceratopsidae and Leptoceratopsidae and more derived clades as in the case of Ceratopsidae). For the rest of the Cretaceous, Ceratopsia experienced a significant increase in its number of species. Consequently, paleontologists subclassify Ceratopsidae into Centrosaurinae (e.g., *Centrosaurus*, *Pachyrhinosaurus*) and Chasmosaurinae (e.g., *Chasmosaurus*, *Triceratops*).

A second Cerapoda lineage, Ornithopoda, originally featured small bodies and typically walked in an upright position (e.g., *Hypsilophodon*, *Thescelosaurus*, *Dryosaurus*). The majority of these lineages are found in Jurassic geological formations. In the Cretaceous, however, multiple derived lineages reached larger sizes and adopted a quadrupedal stance, as in the cases of Iguanodontia (e.g., *Iguanodon*) and Hadrosauria species, such as *Tenontosaurus*, which featured an increase in body mass and the abandoning of a bipedal stance (Brusatte 2012). Akin to Ceratopsia, Hadrosauria also experienced a burst in its total number of species during the Cretaceous. Two main lineages originated during this period: Saurolophinae and Lambeosaurinae. Even though some saurolophine species displayed different types of skull decorations, lambeosaurines (*Parasaurolophus*, *Lambeosaurus*) exhibited more complex forms of cranial ornamentations. Paleontologists continue to debate these crests' evolutionary function, with some suspecting these bony structures acted as resonating chambers, facilitating communication with conspecifics and other organisms (interspecific competitors and predators) (citation needed). Other researchers claim that sexual selection could be the main force behind the evolution of these ornaments (citation needed). Although researchers initially thought hadrosaurs were endemic to North America, Asia, and Europe, contemporary evidence suggests this clade also inhabited various ecologies in South America, Oceania, and Antarctica (Brusatte 2012).

### Paleobiology

After describing the main cladistic classifications of Dinosauria, the upcoming sections will cover four areas of paleobiological research: (1) paleoneurology, (2) life history theory, (3) socioecology, and (4) biogeography. The first section will describe current inquiry into the neuroanatomy of nonavian Dinosauria as well as metrics, such as the encephalization quotient, which are frequently used as proxy variables for emergent cognitive abilities. The second section will offer a brief summary of life history theory and discuss its implications for the understanding of

dinosaurian growth patterns, body size, and life span. The third section, on socioecology, covers several studies on the parental and social behavior of this extinct clade. Lastly, section four reviews multiple analyses exploring the ecological diversification of Dinosauria. This final section will also discuss evidence of niche partitioning involving dinosaurian species found occupying different dimensions of an ecospace.

**Paleoneurology and the Encephalization Quotient.** The encephalization quotient (EQ) is a relative measure for brain size with consideration of a given species' body mass and allometric conditions. It was first expressed formally by H.J. Jerison in 1973 (Jerison 1973) but preceded by the original observation of patterns that Snell speculated to exist when scaling brain mass with body mass (Snell 1891). Later, Dubois' "index of cephalization" increased the specificity of Snell's initial observations and reduced the exponent used for scaling by nearly a third (Dubois 1897). Jerison would go on to challenge Dubois' exponential value but preserve much of the initial framework of his "index of cephalization," eventually yielding the following equation (Jerison and Barlow 1985; Boddy et al. 2012).

$$EQ = (\text{brain mass}) / \left( 0.12 \times \text{body mass}^{(2/3)} \right)$$

0.12 represents a biological constant of average growth. The contested 2/3 exponent provides a value for allometric growth. As seen, this mathematically prioritizes predicted brain size over both observed brain mass and body mass, providing support for the typical usage of EQ in relevant literatures (Boddy et al. 2012).

One of the main issues with this approach to measuring EQ, and thus EQ at large, is the handling of outliers. Since a regression line is produced in the measurement of EQ, researchers must theoretically posit that all species represented underwent comparable evolutionary histories in the development of, and selection for, their particular brain size. Any potential species that may have undergone a different path from their surrounding taxa and therefore today have substantially smaller or larger ratios

of brain-to-body size are automatically excluded from analysis, since lone species cannot be studied using this method. It is only in comparison with evolutionarily similar extinct species, if no other living ones can be identified, that such outliers can be studied using EQ.

Accurate measures of brain size across phylogenies can be challenging to obtain and thus leave researchers with few well-studied species and many that are unknown. EQ attempts to alleviate this problem through a combination of multiple variables, leading to a calculable ratio between known brain mass in observed species and predicted brain mass in unobserved species, as well as the inclusion of allometric predictors. Having been originally designed for the study of mammals, EQ is most commonly used in the analysis of vertebrate species, but some have applied it when studying invertebrates as well.

The EQ measure provides many useful applications. Most fundamentally, EQ refines the understanding of scaling effects on body size for between-species comparisons. Selective explanations can then be proposed for measured differences of quantities that would otherwise be unavailable, allowing researchers to more comprehensively represent physiology, behavior, and other allometric relations in species of interest. Due to a lack of reliable neuroanatomical indicators for intelligence and cognitive complexity in nonhuman species, EQ is also used in studies on cognition and its evolution across phylogenies. Given that all of the variables relevant to EQ can be studied or approximated in both living and extinct species, it has also become a common measurement tool in paleobiology.

A common method employed in paleoneurological studies of EQ first involves the generation of a three-dimensional model of the internal cavity of the skull where the brain is located (Larsson et al. 2000). This rendering, known as an endocast, provides essential data on the volume and structure of different neuroanatomical regions. Carabajal and Canale (2010), for instance, described the endocast of *Giganotosaurus carolinii*, a South American theropod from the Albian-Cenomanian (Coria and Currie 2003). The authors calculated the endocast

volume of *Giganotosaurus* to be 275 mL. The study identified that the endocast achieved its maximum width, 64 mm, at the level of the cerebral hemisphere. The olfactory bulb's length to the foramen magnum measured 29 mm (Carabajal and Canale 2010). Similar to the forebrain of *Carcharodontosaurus*, in *Giganotosaurus*, the cerebrum is located above the cerebellum (Carabajal and Canale 2010). The study also reported that the endocast of *Giganotosaurus* was considerably longer relative to the models described in *Carcharodontosaurus iguidensis* (30% difference) and *C. saharicus* (19% difference).

Franzosa and Rowe (2005) estimated that the endocast of *Acrocanthosaurus atokensis* (Lower Cretaceous, Aptian-Albian) measured 14.88 cm long and exhibited a volume of 190.8 cm<sup>3</sup>. Franzosa and Rowe (2005) calculated the maximum width of the cerebral hemispheres at 4.35 cm. The endocast of *A. atokensis* did not exhibit a pronounced sigmoidal shape but instead resembled the general neuroanatomical appearance of extant crocodylians (Franzosa and Rowe 2005). From these analyses, Franzosa and Rowe (2005) concluded that the brain of *A. atokensis* retained several of the neuroanatomical characteristics observed in ancestral archosaurs. Their study also found that the olfactory bulbs occupied a sizeable portion of the rostral endocranial fossa and reached 6.6 cm in longitude. The olfactory tract started as independent entities merging at the ventral and lateral expansion of the forebrain. The authors determined that *A. atokensis*'s olfactory tract and bulbs' structural organization is consistent with the reported neuroanatomy of other genus of Carcharodontosauridae, such as *Giganotosaurus* and *Carcharodontosaurus*, further supporting the inclusion of *A. atokensis* within this cladistics family. The position of the horizontal semicircular canal indicated that *A. atokensis* tilted its head slightly downward to facilitate the animal's orientation in movement (Franzosa and Rowe 2005).

Brusatte's (2012) review of the literature describes noticeable neuroanatomical differences among Dinosauria clades. According to the author, the endocasts of sauropodomorphs, early

theropods, and ornithischians display morphological similarities with those of extant reptilians. Alternatively, the neuroanatomy of later theropod species resembles, to some extent, those of avian species. In terms of general morphology, endocasts are often classified as either Z-shaped (or S-shaped) or globular. While Z-shaped brains are found across clades of Dinosauria, globular endocasts are generally observed in derived species of theropods, akin to modern birds. For Brusatte, most endocasts in Dinosauria follow a morphological organization which includes the olfactory bulbs and canals occupying the anterior areas, the cerebrum occupying the midpoint, and the cerebellum and brain stem occupying the posterior regions of the brain. The olfactory bulbs' size, measured relative to body size, enabled paleoneurologists to determine that Tyrannosauridae and Dromaeosauridae taxa had exceptional olfactory abilities (Brusatte 2012). In terms of the evolution of olfactory regions, comparative estimations across theropod species concluded that, while some clades had a remarkable sense of smell, this ability was considerably limited in other species, indicating olfaction followed different evolutionary routes in Theropoda (Brusatte 2012). In addition to studies exploring the sensorial abilities of theropods, other researchers have examined the association between neuroanatomy and sociality, wherein estimating the volume of different neural regions has provided insight into the degree of social complexity exhibited in Dinosauria. According to Isles (2009), for example, the telencephalic volume of large theropods, such as *Allosaurus*, *Carcharodontosaurus*, and *Tyrannosaurus*, is equivalent to that of extant reptiles.

Paleoneurologists typically follow the generation of a species' endocast with the computation of its EQ. This metric remains popular because of its ability to consider the positive association between body size and brain size, a link that often confounds an interpretation of correlation with sensory and cognitive functions. Franzosa (2004), for instance, calculated EQ for various theropod and sauropod species. Given that EQ estimates vary depending on the allometric slope associated with different clades, his study

employed two formulas: one based on extant reptilian data (REQ) and a second extracted from extant avian species (BEQ). Consistent with previous publications, the sauropod *Diplodocus* exhibited an REQ value that was slightly lower than that of the extant genus *Crocodylus* (Brusatte's research also identified that sauropodomorphs featured low EQ estimates; 2012). Overall, all theropod species in the sample (including *Ceratosaurus*, *Allosaurus*, *Carcharodontosaurus*, *Acrocanthosaurus*, *Tyrannosaurus*, *Dromiceiomimus*, *Citipati*, and *Troodon*) featured REQ estimates above that of *Crocodylus* but below some avian species (e.g., *Apteryx* and *Anas*). According to Franzosa's calculations, in addition to *Troodon*, *Dromiceiomimus* also displayed high REQ values (relative to other dinosaurs). Franzosa's analyses reached similar conclusions in terms of dinosaurian BEQ. Other publications have reached similar conclusions, wherein maniraptoran theropods, such as *Troodon*, displayed estimates similar to that of some extant avian species (Brusatte 2012).

**Life History and Growth.** Life history refers to how an organism reaches certain milestones during its development (Figueredo et al. 2020). Classical life history perspectives classified species as either *r*- or *k*-strategists (Paul 2016). According to these views, while *r*-strategists feature high reproductive output, leading to population growth, *k*-strategists have few offspring and inhabit populations at carrying capacity (the maximum population size sustained by an ecology). Some researchers have proposed that differential mortality schedules, wherein ecological pressures increase the mortality of a demographic group (e.g., younglings or adults), could explain the observed variation in life history across species. Environments exhibiting high youngling mortality are associated with having multiple offspring, increasing the probability that at least some younglings would survive and reach adulthood.

Alternatively, ecologies displaying considerable adult mortality relate positively with species having relatively few offspring and delaying sexual maturity (van Schaik and Isler 2012). In contrast to large eutherian mammals (exhibiting a long gestation period, a small litter size, and large

neonates), oviparous species, including most reptiles and birds, circumvent the additional costs known to be associated with an internal gestation and are capable of laying large clutches.

Based on the number of eggs per clutch, the literature classifies dinosaurs as *r*-selected species, inferring that young dinosaurs, including hatchlings and juveniles, experienced substantial mortality rates promoting a fast growth to counter the risk of predation (Paul 2016). However, in the past two decades, the *r-k* paradigm has been called into question (van Schaik and Isler 2012). Instead, life history researchers are now exploring alternative theories, including dimensions such as the neoteny-precocial and the fast-slow dimensions (van Schaik and Isler 2012). While the first factor considers the level of developmental immaturity, the second factor encompasses life history indicators such as maximum longevity and fertility (van Schaik and Isler 2012).

Organisms may also allocate resources to at least one of two developmental facets: somatic effort and reproductive effort (van Schaik and Isler 2012). Somatic effort comprises the individual's investment in tissue maintenance, growth, and repair (van Schaik and Isler 2012). Reproductive effort is subdivided into two main subcomponents. The first subcomponent concerns the animal's capacity for searching, courting, and copulating with sexual partners and competing with sexual rivals (i.e., mating effort). The second subcomponent engulfs the individual's parental behavior, including food provisioning and offering protection against predators, parasites, and conspecifics. Consequently, animals continuously face the dilemma of allocating a finite amount of bioenergetic resources to at least one of these life history efforts (somatic effort vs. mating effort, mating effort vs. parental effort, somatic effort vs. parental effort). While little is known in terms of the various types of efforts in extinct Archosauria, it is still feasible to determine some general life history patterns in Dinosauria.

Estimating life tables and calculating the corresponding growth patterns could also explain gigantism in some species of Dinosauria. Erickson et al. (2004) obtained medullar bone samples from juvenile, subadult, and adult specimens of

*Albertosaurus sarcophagus*, *Daspletosaurus torosus*, *Gorgosaurus libratus*, and *Tyrannosaurus rex*. Histological line counting identified that somatic maturity in *T. rex* occurred at approximately 19 years of age, with some individuals reaching maximum longevity at 28 years of age (Erickson et al. 2004). Relative to *T. rex*, *A. sarcophagus*, *D. torosus*, and *G. libratus* attained an earlier somatic maturity (14–16 years) with a slightly shorter maximum longevity (24 years). After computing a series of logistic growth curves, the authors concluded that even though all four species experienced an equivalent duration of the exponential stage, they differed in their growth rates (Erickson et al. 2004).

Erickson et al. (2007), assessed the life history patterns of five nonavian theropods (*Deinonychus antirrhopus*, *Troodon formosus*, *Oviraptor philoceratops*, *Oviraptor* sp., and *Citipati osmolskae*). The authors estimated that *D. antirrhopus* and *T. formosus* reached longevity at 14 and 18 years of age, respectively. The analyses indicated that at least two of the three oviraptorids in the dataset featured similar longevity values (*C. osmolskae* = 13 years; *Oviraptor* sp. = 18 years). *Oviraptor philoceratops* displayed a shorter life span, 8 years, given the specimen perished before attaining full somatic maturity. Because paleontologists discovered the remains of this individual in a brooding position, the results from the osteohistological analyses suggested that *O. philoceratops* attained sexual maturity before reaching somatic maturity.

Erickson's review (2005) of the literature identified considerable variations in the estimated longevity of different species of Dinosauria. Small theropods, such as *Shuvuuia*, had relatively short life spans (approximately 4 years). According to Erickson, saurischian species of moderate size, such as the prosauropod *Massospondylus* or the coelophysid *Coelophysis rhodesiensis* (formerly classified as *Syntarsus*) lived for approximately 7–15 years. For Erickson, larger theropods, as in *Albertosaurus*, nearly doubled the longevity of moderately sized species (24–30 years). Lastly, large sauropods (e.g., *Brachiosaurus*) reached longevity of 50 years of age. Even though additional data is required to conduct statistical

significance tests, Erickson's compendium suggests a positive association between body mass and longevity, a life history covariation observed in other clades.

In addition to saurischian studies, several publications have also examined the growth rates of ornithischians. Noticeable variation existed within this clade in both longevity and growing speed. Brusatte's (2012) assessment of the literature identified that faster growth was not limited to small ornithischians (e.g., *Lesothosaurus*). According to the author, the evidence obtained from ornithopod and ceratopsian specimens also indicates rapid growth. It is worth noting that not all ornithischians followed this life history pattern. Brusatte's (2012) review concluded that thyreophorans, relative to other ornithischians, grew slower. For instance, the limited presence of fibrolamellar tissue in *Scutellosaurus* indicates this species followed a growth pattern akin to that of crocodilians (Brusatte 2012).

Heated debate persists among paleontologists concerning the growth speed in Dinosauria. To date, three main perspectives have been described in the literature. The first hypothesis claims that dinosaurs grew following a general reptilian pattern. Alternatively, the second hypothesis favors avian or mammalian-like growth. The third approach takes a moderate stance, wherein dinosaurs grew faster than reptiles but slower than birds and mammals (Erickson 2005). Erickson's examinations (2005) concluded that, relative to extant reptiles, dinosaurs grew at a faster rate (the analysis accounted for body size). Moreover, larger species tended to reach their fully mature size faster. Hence, Erickson (2005) inferred that dinosaurs featured unique physiologies, as evidenced by their growth rates.

**Parental Behavior.** Given that parental care (such as parents attending to their clutches or investing in their young) is widespread across avian, crocodilian, and mammalian taxa, it is expected that at least some species of Dinosauria actively invested in their offspring. The fossil evidence collected in the past six decades indicates that a set of species akin to extant Archosauria performed parental behaviors. Notably, the fossils of at least two genera of

oviraptorosaurs – *Citipati* and *Oviraptor* – have been found nesting (Varricchio 2011). Paleontologists have also inferred parental care based on the physical proximity between the remains of adults and juvenile individuals, including the genus *Patagosaurus*, *Psittacosaurus*, and *Tenontosaurus* (Varricchio 2011). This pattern extends to maniraptoran theropods, whereby paleontologists discovered adult specimens of the genus *Troodon* and *Deinonychus* close to their respective nests (Varricchio 2011). Other dinosaurian species known to form assemblages of older juveniles include the theropod *Sinornithomimus* and the ornithopod *Edmontosaurus* (Varricchio 2011).

Debate persists concerning the prevalence of parental behaviors in other theropods. According to some publications, the osteological and taphonomic evidence supports the presence of parental behavior in *Allosaurus fragilis*, wherein adult and juvenile teeth have been recovered near skeleton prey, indicating that adults dragged the carcass to a lair to be consumed by younger individuals (Isles 2009; Varricchio 2011). Other researchers remain unconvinced by this evidence. Isles (2009) proposed that multiage *Allosaurus* congregations, rather than providing compelling evidence of parental behaviors, suggested cannibalism. Additional data is required to settle the enigma of parental care in large theropods.

Despite the absence of adult remains, some researchers have interpreted hatchling assemblages as an indication of parental care (Varricchio 2011). For instance, Horner discovered multiple *Maiasaura* eggs and hatchlings, a cretaceous ornithopod, within nest-like structures (Horner 1999). The younglings' osteological immaturity indicated a semi-altricial development and limited levels of autonomy (Varricchio 2011). This pattern, generalized to other ornithischian species, such as the ceratopsian *Protoceratops*, wherein hatchlings recovered from Late Cretaceous strata in Mongolia, displays signs of an altricial development (Varricchio 2011; Weishampel et al. 2000). Given that avian altricial and semi-altricial species often exhibit parental care (Shultz and Dunbar 2010), it is probable

that *Maiasaura* and *Protoceratops* also exhibited this behavioral phenotype.

Sauropod parental care remains a topic of intense scrutiny. The debate persists partly due to the current ichnological record supporting the hypotheses that at least some sauropod species were gregarious, with groups ranging from three to approximately 20 animals (Myers and Fiorillo 2009). Paleontologists have found sauropod trackways worldwide, including parts of modern-day China, Portugal, Brazil, Bolivia, the United Kingdom, and the USA (Myers and Fiorillo 2009). The literature also describes noticeable variation in the composition of these groups. While some trackways exhibit signs of adult and juvenile aggregations, the footprints described in other paleontological sites are exclusively of adults. Myers and Fiorillo (2009) assembled a comprehensive ichnological database suggesting age-segregated groups such as (1) at least 40 adults in the United Kingdom; (2) six adults in Colorado, the USA; (3) approximately ten adults in Texas, the USA; and (4) ten adults in Arkansas, the USA. The authors also reported juvenile and subadult assemblages: (1) five juveniles in Colorado, the USA; (2) three juveniles in Utah, the USA; (3) four juveniles in China; (4) seven subadults in Portugal; and (5) 11 subadults in Bolivia. According to Myers and Fiorillo's database, the ichnological data also supports mixed-age groups in some sauropod species: (1) five individuals in Brazil; (2) 23 animals in Texas, the USA; and (3) eight individuals in Bolivia.

The fossil evidence also supports the fact that some sauropod species lived in age-segregated groups (Myers and Fiorillo, 2009). Some examples include (1) at least six adult *Barapasaurus* in India; (2) more than 12 adult *Kotasaurus* in India; (3) at least four adult *Paluxysaurus* in Texas; (4) approximately 17 juvenile *Bellusaurus* in China; (5) eight juvenile *Diplodocoidea* in Montana, the USA; and (6) more than three juvenile *Alamosaurus* in Texas, the USA. Alternatively, evidence of mixed-age groups consists of (1) the remains of five *Patagosaurus* uncovered in Argentina, (2) over 12 *Europasaurus* in Germany, and (3) approximately five *Brachiosaurus* in

Tanzania. In light of this evidence, Varricchio et al. (2008) estimated the probability of paternal care in Dinosauria. The authors obtained life history data (body mass and clutch volume) on 433 extant avian and crocodilian species and three extinct maniraptoran theropods, *T. formosus*, *O. philoceratops*, and *C. osmolskae*. The data were disaggregated based on the type of parental care: (1) bird maternal, (2) bird paternal, (3) bird biparental, and (4) crocodilian maternal. Subsequently, the authors computed a series of bivariate regressions between log body mass and log clutch volume and used the Akaike information criterion (AIC) to determine which model fitted the maniraptoran values. The model comparison identified the avian paternal care model as having the best fit.

**Social Behavior.** Currie and Eberth (2010) considered five primary sources of evidence supporting the presence of gregarious behavior in Dinosauria: morphology, fossil assemblages, trackways, phylogenetic reconstructions, and inferences based on modern ecologies. According to the authors, the presence of morphological ornamentation in numerous dinosaur species suggests at least occasional interactions (intrasexual competition, intersexual selection, socialization) between conspecifics. For instance, numerous ornithomorphs (Hadrosauria) and marginocephalians (pachicephalosaurians and ceratopsians) feature cranial protrusions that could have been used in sexual contests or displays. This pattern also appears to have extended to various theropod species. Coelophysoids (*Dilophosaurus*, *Zupaysaurus*, *Monolophosaurus*), abelisaurids (e.g., *Carnotaurus* and *Majungasaurus*), ceratosaurids (*Ceratosaurus*), tyrannosauroids (*Proceratosaurus*, *Guanlong*), spinosaurids (*Spinosaurus*, *Irritator*), oviraptorosaurs (*Oviraptor*), and allosaurids displayed cranial crests, ridges, and horns (Currie and Eberth 2010).

Although the subject of theropod fossil assemblages as an indicator of dinosaur gregariousness remains a controversial topic, the physical proximity of conspecifics in the absence of other species suggests some theropod species behaved gregariously (Currie and Eberth 2010). For example, the authors discovered at least 12 *Albertosaurus*

in Dry Island, Canada. Given that large adult carnivores, as in the case of tyrannosaurids, required a vast home range (approximately 200 km<sup>2</sup> per individual), Currie and Eberth concluded that gregariousness, rather than the independent congregation of individuals, offers a more parsimonious explanation to the observed fossil assemblage. The absence of taphonomic markings in the remains of the 12 specimens falsified alternative hypotheses, such as cannibalism. Likewise, the authors remained unconvinced regarding perspectives claiming that these assemblages were the product of solitary individuals flocking around carrion. In addition to *Albertosaurus*, the literature describes at least four instances of tyrannosaurids found close to each other. The first two correspond to Mongolian quarry sites featuring at least two specimens of *Tarbosaurus*; the third quarry, found in South Dakota, the USA, contained the fossils of four *Tyrannosaurus*. Similarly, paleontologists extracted three *Daspletosaurus* from a bone bed located in Montana, the USA.

Dinosaur gregariousness is not exclusive to Cretaceous tyrannosaurids. The literature describes (Currie and Eberth 2010) three Triassic sites containing the bodies of coelophysoids. At Ghost Ranch, the USA, researchers identified approximately 1000 *Coelophysis bauri*. Similarly, paleontologists unearthed 26 *Syntarsus rhodesiensis* (nowadays relabeled as *Coelophysis rhodesiensis*) close to Zimbabwe's Chitake River. Lastly, researchers recovered two *Liliensternus liliensterni* from the Knollenmergel, Germany. Early Jurassic theropods retained their ancestor gregariousness. In Arizona, researchers described two *Dilophosaurus wetherilli* in relative proximity (Currie and Eberth 2010). Four *Syntarsus kayentakatae* were also recovered from another Jurassic Arizonian location. Conspecific congregations were not exclusive of small- and medium-size theropods. The literature describes two sites featuring Late Jurassic animals. In Kenton, Oklahoma, paleontologists identified four *Saurophaganax maximus*, a large allosaurid (some estimations indicate some animals could reach up to 14 meters long; Currie and Eberth 2010).

In a similar vein, the paleontological literature describes skeletal assemblages of other theropod species, including carcharodontosaurids. In

Argentina, a paleontological expedition identified nine *Mapusaurus* in Cañadón del Gato (Currie and Eberth 2010). This finding still generates intense debate regarding the presumed sociality of large theropods. Currie and Eberth (2010) clarified that multiple individuals' presence does not suggest that all theropod species lived gregariously. On the contrary, Currie and Eberth (2010) emphasize that researchers should examine any claim of sociality on a case-by-case basis, an essential recommendation considering that even closely related taxa occasionally feature different social organizations.

Trackways are yet another source used for inferring conspecific gregariousness and demographic compositions of groups behind the fossilized footprints. The Toro Toro site in Bolivia, a Late Cretaceous paleontological site, is a clear example of multiple individuals traveling together (Currie and Eberth 2010). This paleontological site features two trackways, each one displaying the coordinated movement of early theropods. The ichnological analyses estimated that approximately 60 animals of the same species generated the footprints at Toro Toro. Other Cretaceous theropod trackways include the Ponta da Guia site in Brazil, where at least four individuals seem to have traveled together, and Fuente Salvo, in Spain (12 conspecifics; Currie and Eberth 2010). This pattern extends to other geological periods. For example, two Middle Jurassic sites, the Chewore formation in Zimbabwe and the Isle of Skye site in the United Kingdom, display the footprints of multiple individuals (current calculations estimate at least five individuals on each site; Currie and Eberth 2010).

**Paleoecology and Biogeography.** Zoogeography, a subdiscipline of biogeography, comprises the study of species distribution and variety in past and present land regions. Sclater (1858) and Wallace (1876) provided foundational hypotheses that would later develop into the present field, considering such topics as regional variation in ecology, such as temperature and altitude, and its effects on the evolution of traits, such as predation, competition, and parasitism, across species. Further, species distribution was found to involve matching between species and environment, as

geographical barriers and species-specific traits both impact the likelihood of non-native species succeeding in novel environmental conditions (Wallace 1876). Hertler et al. (2018) recently built upon Wallace's view, finding that full assemblages of symbiotic species can be impacted by environmental pressures, not solely native species.

The early study of physical ecology comprised the use of latitude and longitude alone as indicators (Johnston 1850). Sclater (1858) crucially added species variation to demarcate regions in further depth. This began with a study of the regional prevalence of avian species across observable land areas, leading to the specification of six unique zoogeographic regions. Wallace (1876) expanded Sclater's construction, placing four additional subregions within each main region, based on whether or not transition zones were present and the degree of within-region variation. These original categories have largely stood the test of time, despite differing perspectives from some in zoogeography and relevant literatures (Figueroa et al. 2020).

In a recent review, Morrone (2015) hierarchically classified modern-day regions cited within the biogeographic, zoogeographic, and phytogeographic literatures from 1850 through 2010. His findings indicated, first, consensus around the naming of three kingdoms and nine regions: the Holarctic kingdom (containing the Nearctic and Palearctic regions), the Holotropical kingdom (containing the Neotropical, Ethiopian, and Oriental regions), and the Austral kingdom (containing the Cape, Andean, Australian, and Antarctic regions). Further, Morrone (2015) identified five transition zones, which, following Wallace's original conception of their importance, continued across time to permeate relevant literatures. Those zones were the Mexican (Nearctic-Neotropical transition), Saharo-Arabian (Palearctic-Ethiopian transition), Chinese (Palearctic-Oriental transition), Indo-Malayan (Oriental-Australian transition), and South American (Neotropical-Andean transition) (Morrone 2015). It is necessary to note that in a paleogeographical setting, the naming and relative locations of these regions are subject to substantial modification across time. However,

affirmation of the principles dictating Wallace's contributions to their classification – namely, the addition of transition zones and within-region variation – is unavoidably established using contemporary regions because of the relative ease with which one can study many organismic variables that are not easily investigated using ancient fossil records.

Wallace's original conception of species distribution relied on the documentation of ancestral relationships across species. More recently, however, species distribution is studied through the analysis of phylogenetic effects (Avice 2008). Holt et al. (2013) classified, according to phylogenetic proximity between species, the zoogeographic distribution of 21,037 species of amphibians, birds, and mammals. The study resulted in the identification of 20 distinct zoogeographic regions, which were further grouped into 11 overarching realms (Holt et al. 2013). These findings, among others, continue to largely support findings resulting from the hypotheses of Wallace and Sclater centuries before. Some differences in the characterization of certain areas did persist, however, such as insular regions of the Oceanian realm as well as the Saharo-Arabian realm and its intermediate positioning between the Afrotropical and Sino-Japanese realms (Holt et al. 2013).

The concept of an ecological niche revolves around the behaviors of organisms – both individuals and social groups – within a specified environment and the relationships among relevant biotic and abiotic components of that environment with those organisms (Pocheville 2015). These relationships impact the types of, and competition rates for, resources among inhabitants of the environment. Further, the organism's individual capacity to compete within, and thus preferentially construct, their niche determines the variety of resources they are able to utilize. This principle is known as their *niche width* (Roughgarden 1972). Smaller niche widths demarcate *specialist* species, whereas larger niche widths demarcate *generalist* ones (Roughgarden 1972).

Species appear to evolve toward either a specialist or a generalist strategy for a variety of reasons. First, the fitness consequences of the

variety of resources used by a species appear to depend on the trade-off between performance with one resource and the performance cost when introducing a second resource (Levins 1968). Generalist strategies are considered favored when a species is adapted somewhat equivalently to the utilization of multiple resources. Specialist strategies, in contrast, are considered favored when a species is primarily adapted to the utilization of one resource or resource type, meaning that they lack the capacity to productively forage for, or make use of, other available resources nearby. Therefore, minute alterations to the availability of resources negatively impact specialist species substantially more than generalist ones, who possess a buffer to such ecological fluctuations (Bonsall and Wright 2012). Fry (1996) argues that, as a result, selection for specialist strategies depends on positive selection for the traits underlying use of one resource and concurrent weaker positive, or neutral, selection on those traits involving other resources.

The nature of the coexistence between consumers of the same resource also impacts the likelihood of selection favoring generalist versus specialist strategies (Bonsall and Wright 2012). For those species favoring generalist strategies, cooperation with other consumers of the same resources increases the likelihood of preserving continued access to multiple resources, for all participating species (Chaneton and Bonsall 2000). In the opposing scenario, competition may decrease the success of cooperative behaviors, thus favoring both specialism and decreased competition (Platt and Bever 2009; Bonsall and Wright 2012). One tactic influencing this form of coexistence is resource partitioning (Miller 1967). Exclusive resource rights, herein, decrease the likelihood of competition between species and increase that of coexistence (Hunt and Bonsall 2009). Further, coexistence among multiple specialist species relies on life history trade-offs favoring diversification and constraining similarity in morphology or strategy. This is often, but not universally, a result of disruptive selection (Bonsall and Wright 2012). Phylogenetic analyses have provided support for this notion of an

increase in likelihood of specialist strategy with diversification processes (Schluter 2000).

**Dinosaur Zoogeography and Niche Partitioning.** Recent paleontological publications have also explored the distribution of dinosaur species across the globe. The phylogenetic proximity of taxa found in different continents offers some insight into the potential continental location of the last common ancestor of particular species. A classic example is the presence of abelisaurids, spinosaurids, and carcharodontosaurids in Africa and South America, indicating the ancestors of these clades probably originated in the southern supercontinent Gondwana, after the fragmentation of Pangea (Brusatte 2012). For species found in the continental remnants of Laurasia (constituting modern-day North America, Europe, and Asia), cladistic estimations identified that North American taxa (e.g., Tyrannosauridae) are phylogenetically closer to Asian, rather than to European, species (Brusatte 2012). This pattern is expected because, contrary to contemporary Europe, encompassing a large continental mass attached to Asia, Europe during the Cretaceous was mostly composed of numerous islands occasionally interconnected through shallow waters and temporary land bridges during the Cretaceous.

Farlow and Planka (2002) offer a compelling case regarding habitat partitioning and morphological variation in extinct Dinosauria. The authors reviewed the literature and gathered body mass and skull size information on various predatory species, including Australian varanid lizards, crocodilians, extant avian raptors, carnivorous mammals (their review encompassed both extant and Plio-Pleistocene carnivores), and theropod dinosaurs. The author's examination with the non-dinosaurian species determined that taxa inhabiting the same environment featured noticeable differences in body mass. The authors also concluded that large-bodied species occupying similar dietary niches exhibit other morphological differences associated with predatory behavior. Interestingly enough, smaller species, members of the same trophic guild, were less dissimilar to each other in skull and body size than larger species occupying similar ecological niches. The study also concluded that similar-sized species could

coexist in the same habitat under certain conditions as long as their dietary niche did not overlap. Lastly, the study concluded that they tend to either occupy specialized microhabitats or segregate geographically in circumstances wherein guild members feature similar body size and predatory morphology.

Following the identification of these evolutionary patterns, Farlow and Planka proceeded to explore similar dynamics in extinct theropod taxa. Their study included seven Late Cretaceous species: *Gorgosaurus libratus*, *Daspletosaurus* sp., *Chirostenotes pergracilis*, *Troodon formosus*, *Dromaeosaurus albertensis*, *Avimimus* sp., and *Sauronitholestes langstoni*. The analyses estimated a large skull length ratio for the pairs *Gorgosaurus-Troodon* (~4.5 ratio) and *Dromaeosaurus-Avimimus* (~3.0 ratio). Alternatively, the remaining pairs *Daspletosaurus-Gorgosaurus* and *Troodon-Chirostenotes* exhibited skull size ratios below 1.5. Regarding body size, Farlow and Plank calculated a substantial ratio between *Daspletosaurus* and *Chirostenotes* (~35.00). Based on these results, the authors determined that large carnivores, such as *Daspletosaurus* and *Gorgosaurus*, displaying similar morphologies, avoided direct competition by either specializing on different prey (*Daspletosaurus* preferred to hunt ceratopsians, whereas *Gorgosaurus* hunted hadrosaurs) or occupying nonoverlapping micro-niches. The more significant number of *Gorgosaurus* ( $n = 23$ ), relative to *Daspletosaurus* ( $n = 7$ ), found at the Dinosaur Park Formation in Canada, suggests these species did not interact frequently. Additional biogeographic studies have found that *Daspletosaurus* generally inhabited Southern North American ecologies, whereas *Gorgosaurus* preferred Northern regions. These results are consistent with Farlow and Planka's discovery of niche partitioning in extant predators.

In more recent publications, researchers have explored the relation between various lithological formation types and different species of dinosaurs. Lyson and Longrich (2011) reviewed the paleontological literature and assembled a comprehensive database containing information on

the sediment conditions found close to recovered dinosaur specimens in Late Cretaceous North America. The sample includes 343 individuals, 149 associated with mudstone and 194 with sandstone. The authors computed a series of chi-square tests and identified a positive association between the frequency of hadrosaurs and sandstone. Alternatively, most ceratopsian specimens were found in mudstone sediments. The analyses, however, did not detect a significant association between ornithomimosaurids and particular lithological formation. The number of *Tyrannosaurus rex* specimens did not differ in either sandstone or mudstone sediments. These results strongly suggest that populations of *T. rex* persisted and thrived across a variety of environments.

Further publications have also explored the presence of niche partitioning among herbivorous dinosaur species extracted from the Dinosaur Park Formation. Mallon and colleagues (2013) considered the hypotheses that folivorous species avoid direct competition by feeding at different heights. The study, however, did not detect evidence of feeding stratification based on height. Most of the species in the sample forage near the ground. Hadrosaurs were the only clade able to feed on small trees. The authors also concluded that the bipedal and quadrupedal stance of sympatric species of Hadrosauria reduced the intensity of feeding competition. Overall, the analyses concluded that, besides feeding stratification, other forces favored niche partitioning across Late Cretaceous ecosystems in North America.

In addition to complete remains, taphonomic and morphological studies offer further evidence of niche partitioning. Frederickson, Engel, and Cifelli (2018) assessed the diversity of North American Cretaceous predators at the Mussentuchit formation in Utah, the USA. The researchers compared the tooth morphology of multiple theropod species. The study gathered samples from six sites and identified four tooth morphotypes including Richardoestesia-like teeth and those of a small-sized dromaeosaurid, medium-size dromaeosaurid, and a large-bodied theropod. The analyses identified that Richardoestesia-like teeth were generally found close to water channels. The teeth of medium-

size dromaeosaurids were more frequently found in floodplains, whereas the teeth of both large-bodied theropods and small-sized dromaeosaurids were more abundant in channels and floodplains. According to the authors, this evidence supports the hypothesized division of the ecospace among Mussentuchit's theropods.

Isotopic assessments further support the division of ecospace among species of Dinosauria. Fricke and Pearson (2008) calculated the ratio of isotopes in a single element ( $\delta$ ) found in the enamel of various dinosaur species. This value conveys information on the water and plants each animal consumed during its lifetime. The authors computed  $\delta^{18}\text{O}$  and  $\delta^{13}\text{C}$  for multiple species of Ceratopsia and Hadrosauria recovered from the Hell Creek Formation in the USA. The project determined that these two clades displayed different isotopic signatures, supporting the hypothesis that the dietary niche of these clades did not overlap. Fricke and Pearson's review of the literature determined that, whereas high isotope estimates are often associated with open habitats, low values are found in canopy-type habitats. Based on these ecological and chemical patterns, the authors inferred that ceratopsians and hadrosaurs also inhabited different environments, with hadrosaurs preferring closed canopy settings and adult ceratopsians preferring open habitats.

Paleontologists have likewise found evidence of niche partitioning in Upper Jurassic Dinosauria. Henderson (1998) contrasted the skull and tooth morphology of large carnivorous dinosaurs collected from the Upper Jurassic Morrison Formation in the USA. Henderson's sample included various specimens of *Allosaurus* and *Ceratosaurus*. The comparative exploration identified two *Allosaurus* morphs. The first one featured a short and robust skull, whereas the second one exhibited a longer crania. *Ceratosaurus*, a medium-sized theropod, also displayed a compact skull. The authors interpreted the anatomical variation between *Ceratosaurus* and long-skulled *Allosaurus* to be an indication that these species relied on different predatory strategies. This pattern did not, however, extend to *Ceratosaurus* and robust-skull *Allosaurus*. Henderson interpreted the presence of robust-skull *Allosaurus* and the

absence of *Ceratosaurus* in certain locations as evidence of ecological competition and displacement. Besides their exploration of interspecific ecological interactions, Henderson's study provides further proof of niche splitting occurring within theropod species.

## Evolution of Dinosauria and Mesozoic Extinctions

Even though the Cretaceous-Tertiary mass extinction (i.e., KT event), leading to the demise not only of nonavian Dinosauria but also of Pterosauria, Plesiosauria, and Pliosauria clades, still captures the public's imagination, at least six additional extinctions occurred during the Mesozoic. Researchers dated the earliest event, referred to as the Carnian Pluvial transition, around 234 million years ago (Dal Corso et al. 2012). The sedimentological evidence suggests that both global climate variations, geological uplifting, and volcanism (e.g., flood basalts in Wrangellia, a terrane located in Northwestern North America) led to the disappearance of a multitude of invertebrates and primitive chordates. Paradoxically, basal species of Dinosauria, including *Eoraptor*, evolved under these challenging conditions (Brusatte 2012). Approximately 201 million years ago, almost 50 million years after the massive Permian-Triassic extinction (an event that eliminated over 90% of all marine life), the earth once again face a major extinction. This time, the Triassic-Jurassic mass extinction (TJ) eliminated close to 40% of all terrestrial tetrapods. The elimination of numerous archosaur and mammal-like reptiles enabled dinosaurs to occupy these recently vacant ecological niches. Current explanations claim that either volcanic eruptions (flood basalts associated with Central Atlantic Magmatic Province; Tanner et al. 2001) or climate change caused the TJ event (Quan et al. 2008). Although some researchers have also considered an asteroid or comet collision as an alternative explanation, to this date, no extraterrestrial crater matches the dates of the TJ extinction.

The Toarcian event, dated approximately 180 million years ago (Early Jurassic), mainly affected marine fauna (e.g., fish, crustaceans, and

marine reptiles), sparing most dinosaurian clades. The elimination of oceanic species suggests that changes in marine oxygenation or acidification, perhaps linked to volcanism (Karoo-Ferrar flood basalt; Pálffy and Smith 2000), caused this extinction. Close to 40 million years after the Toarcian, the Tithonian transition during the Late Jurassic (145 ma) saw a reduction in the number of theropod species (Tennant et al. 2017). Interestingly, contemporary research found noticeable continental differences in diversity loss, with Laurasia, relative to Gondwana, exhibiting a more pronounced decline in the number of species. Fossil counts also suggest that medium-sized, large-bodied theropods were especially susceptible to extinction, as was the case for megalosaurids, ceratosaurids, piatnitzkysaurids, and allosaurids (Tennant et al. 2017). Alternatively, carcharodontosaurids, neovenatosaurids, spinosaurids, tyrannosauroids, troodontids, and dromaeosaurids managed to survive into the Cretaceous. In contrast to other theropod clades, Paraves experienced accelerated radiation leading to multiple novel species during this transition. Even though paleontologists estimate sauropods reached their diversification maximum in the Late Jurassic, the fossil record evidences a sudden reduction in the number of species during the Jurassic-Cretaceous boundary (Tennant et al. 2017). Except for North America, the number of Brachiosauridae taxa fell dramatically worldwide (Tennant et al. 2017).

Around 117 million years ago, corresponding to the Aptian age (Early Cretaceous), India's Bengal region experienced a significant increase in volcanic activity (i.e., Rajmahal traps; Singh et al. 2004). Additionally, a second Cretaceous mass extinction occurred approximately 95 million years ago (Cenomanian-Turonian boundary). Some paleontologists and geologists claim that a rise in volcanism of two igneous provinces, located in the Caribbean and Madagascar, matches a decline in oxygenation during this time. These fluctuations caused the loss of numerous marine reptiles, including ichthyosaurian and pliosaurian taxa (Sachs and Grant-Mackie 2003).

The last Cretaceous extinction, the KT event, has been described in great detail over the past three decades; paleontologists have generated

multiple hypotheses concerning the causes of Cretaceous-Paleogene extinction, including gradual climate change, volcanism, and cosmic collisions. The current scientific consensus posits that nonavian Dinosauria, along with other archosaurs such as pterosaurs, plesiosaurs, and non-archosaurian marine reptiles, disappeared along with 75% of all life on earth approximately 65 million years ago.

Alvarez and colleagues detected high concentrations of iridium in KT sediments (Schulte et al. 2010). Given this material's rarity close to the earth's crust, the authors hypothesized a collision with a 15 km-wide asteroid occurred during the Cretaceous-Paleogene transition. Although initially considered a controversial claim, the subsequent discovery of a Late Cretaceous crater in Chicxulub (100 km in diameter), close to the Yucatan peninsula, provided strong support for Alvarez and colleagues' hypothesis (Schulte et al. 2010). The immediate consequence of this collision included severe earthquakes with a magnitude above 11 points on the Richter scale, megatsunamis covering coastal lands, and the ejection and spread of geological material to the atmosphere, reentering as spherules leading to the ignition of local wildfires around the Gulf of Mexico (to this date, the evidence does not support the claim of large fires occurring at a global scale; Schulte et al. 2010). The collision also expelled gases, dust, and water into the atmosphere, substantially modifying the climate. According to Schulte and collaborators (2010), the ejection of sulfur produced acid rain and led to a global decline in temperature (10 °C) for several years. Despite these alternations, the oceanic sediment did not exhibit an increase in marine acidification (Schulte et al. 2010).

## Discussion

Paleobiological reconstructions offer strong evidence of similarities the clade Dinosauria shared with extant tetrapods, from similar neuroanatomical organizations with reptilians and avian taxa to parental and social behaviors. To this date, the paleontological record supports the hypothesized

presence of paternal care in at least some theropod and ornithopod species. Likewise, it also suggests that dinosaurs differed in numerous aspects from contemporary species. Although researchers generally classify Dinosauria as an *r*-selected clade, the growth rate and gigantism of certain species have not evolved in other taxa during the evolutionary history of this planet. Similarly, osteological and histological analyses indicate the metabolism of these creatures did not follow either a strict reptilian or mammalian pattern. Concerning the multiple mass extinctions that occurred during the Mesozoic, the literature reveals that, while the Cretaceous-Paleogene event brought the reign of Dinosauria to a close, other ecological disruptions laid the foundations for their evolutionary success. The Late Triassic extinction, for example, eliminated multiple predators and competitors of Dinosauria, vacating many ecological niches and facilitating the rapid species radiation of this clade. Additional, environmental changes also accelerated species turn-out, leading to the noteworthy diversity of this now extinct clade.

## Paleontology

David A. T. Harper

Palaeoecosystems Group, Department of Earth Sciences, Durham University, Durham, UK

Paleontology, the study of ancient life, is a multi-disciplinary science. The fossil record provides a unique long-term view of the evolution of our planet and its biosphere, an insight into the extraordinary extinct organisms that have inhabited the Earth; it also informs us about global change through deep time and helps provide predictions for the future of life. Paleontology is a unique dimension of human thought, involving planetary evolution through deep time and speaks to our origins and place in the Universe. It has advanced as a science from a mainly descriptive subject based on careful taxonomy of fossil animals and plants by specialists to one relying heavily on the newest technologies to scan and analyze fossil material, from microscopic plankton to the skulls of the largest dinosaurs. Data on the morphology of fossils and their geographic and temporal ranges are now the components of

big databases; these form the basis for the reconstruction of phylogenies, and their calibration against geological time scales, as part of the Tree of Life. They also provide information to frame and test hypotheses on the long term and large-scale patterns and processes of the evolution of life in deep time. Nevertheless, our understanding and use of fossils have also provided fundamental evidence for tectonic processes, the movement and collision of continents through time, and the assembly of mountain belts.

How do we comprehend these alternative worlds in deep time, populated by animals and plants quite different from those of today? Worlds populated by dinosaurs with colored feathers; giant rats, weighing a ton; miniature human species; and frightening millipedes and sea scorpions exceeding the size of the tallest humans. The cast of a science fiction movie? No, the products of some four billion years of evolution. It is a story that only humans can attempt to unravel. Our understanding is based on scientific methodologies. Thomas Kuhn (1922–1996) proposed that science advances by paradigm shifts; in earth sciences the formulation of the theories of evolution and plate tectonics and possibly the meteorite impact at the end of Cretaceous sparked scientific revolutions. However, Karl Popper (1902–1994) argued that in science, proof is impossible; the best we can do is to continue to frame and test hypotheses that corroborate the available data and cannot be falsified. That is very much the methodology of paleontological research where data are generally incomplete.

## History

The early Greek historians and natural scientists, for example, Xenophanes (576–480 BC) and Herodotus (484–426 BC), recognized that some fossils were the remains of marine organisms. Xenophanes concluded that water must have once covered the Earth, whereas Herodotus suggested that the fossils in the hills of Egypt indicated that an arm of the Mediterranean extended southwards over the country. The

Romans, however, preferred to record fossils instead as magical objects.

During the Renaissance, Leonardo da Vinci (1452–1519), the supreme polymath, used his knowledge of living animals and plants to explain the occurrence of shell beds in the hills of Lombardy in terms of once living shell banks now preserved, at four levels, in sandstones. Elsewhere, already fossils were being captured in cabinets of curiosity in the homes of the aristocracy; Conrad Gesner (1516–1565) displayed his fossil objects to good effect, whereas Johann Kentmann's (1518–1574) Ark or Cabinet resembled a well-organized museum with fossils recorded under stones and wood embodied in rocks. The notion that fossils somehow grew in the rock propagated by plastic forces continued to

prevail and was promoted by Robert Plot (1640–1696) and some of his contemporaries.

Nicolaus Steno (1638–1686), better known to geologists for his law of superposition of strata, established without doubt that fossil teeth or glossopetrae (tongue stones) he collected in the Tertiary rocks of the Italian Apennines were in fact identical to those of modern sharks landed from the nearby Ligurian Sea (Fig. 1). While in Britain, Robert Hooke (1625–1703) compared the structures seen in fossil wood (charcoal) with those seen in living trees, under the lens of a crude but effective microscope. Hooke also recognized the fact that organisms, such as ammonites, were now extinct. A critical component is the understanding of deep time. The planet did not originate thousands of years ago, but rather

#### Paleontology,

**Fig. 1** Nicolaus Steno's (1667) comparison of the head of a living shark (above: "head of a sea fish") and fossil shark teeth (below: "its teeth")

billions of years ago. James Hutton (1726–1797) provided the basis for understanding the planet's long and eventful history (Repcheck 2003). Paleontology picked up pace in the nineteenth century. George Cuvier (1769–1832) recognized horizons of mass extinctions or catastrophes in the Tertiary rocks of the Paris Basin. A significant part of Charles Darwin's *On the Origin of Species* (1859) was devoted to geology and the fossil record, whereas a year later John Phillips (1860) published a database of fossil ranges and diversity curves through time in *Life on Earth*. From these key discoveries sprang a number of key concepts not least those of evolution, extinction, and mass extinctions and subsequent studies built on these fundamental works. During the latter part of the nineteenth century and early part of the twentieth century, a continued focus on taxonomy and classification of fossil organisms was supplemented by some studies of the life modes and habitats of fossil organisms together with the recognition of recurrent assemblages and associations of animals and plants.

From the mid-1960s onwards, the science of paleontology began to change; there was a greater emphasis on community ecology and large-scale change through time. With the wider availability of computers, big databases were assembled for morphological analysis and for fossil range data throughout the Phanerozoic (Hammer and Harper 2006). X-ray scanning revealed much of the internal structures and the composition of many fossil organisms, particularly vertebrates, and molecular data were aligned with fossil data to construct and calibrate phylogenies. New discoveries and new techniques allowed paleontologists to pursue a much more scientific agenda and tackle much more interesting questions.

## Preservation

The fossil record is manifestly incomplete and biased but is more than adequate to document the key patterns and processes of the history of life. The eminent Victorian zoologist Thomas Huxley described the fossil record as “the skimmings of the pot of life.” Some 250,000 fossil

species have been described in contrast to the tens of millions of living species we have today. There is clearly a major disparity in numbers accounted for by the vagaries of fossil preservation. The science of preservation is normally called taphonomy and targets the processes of decay and preservation of an organism following its death (Allison and Bottjer 2010). The hard tissues of animals and plants are most usually preserved in the fossil record, since soft tissues and soft-bodied organisms rapidly decay during the transport and subsequent of dead organic material. Hard tissues commonly skeletons are preserved as molds, when the shell is dissolved or may be recrystallized as another substance or be partially or completely replaced by mineral material.

Occasionally, however, entire communities are preserved including the soft parts of skeletal organisms and soft-bodied organisms themselves (Briggs 2003). These exceptionally preserved biotas or Konservat-Lagerstätten preserve snapshots of the history of life. The life modes of these organisms, their affinities with other groups, and their place in food chains can be much better understood and graphically reconstructed. A large number of Lagerstätten are clustered around the lower and middle Cambrian, the most famous being the Burgess Shale (Canada), Chengjiang (China), and Sirius Passet (Greenland). In some fossils not only the guts and their contents are preserved but also muscle and nerve tissues and portions of the brain (Fig. 2). These discoveries expose much information about the origins and diversification of early animal-dominated, marine communities.

Paleontology is traditionally considered a sub-discipline of geology and is usually located in earth science departments and institutes. Paleontological data are derived from a number of sources: body fossils, the preserved bones and shells of organisms, and the behavior patterns left in the sediments (Fig. 3). The increasing relevance of fossils, however, to understanding biological processes and a greater alignment with the work of molecular biologists and paleontologists has seen a greater association with biological science departments.

**Paleontology, Fig. 2** Types of preservation in the early Cambrian Sirius Passet Lagerstätte, North Greenland. **a**, Trilobite *Buennellus*, hard parts preserved, sometimes in silica; **b**, a giant trilobitomorph *Arthroaspsis*, mold of soft parts showing a central gut and mining burrows produced by organisms feeding on the carapace; **c**, onychophoran

P

## Evolution

Life has been diversifying and evolving on Earth for at least 3.8 billion years. The key model of natural selection, championed by Charles Darwin (1859), has been validated and hardened in all branches of biology (Futuyma and Kirkpatrick 2017). His observations on the fossil record that animals and plants changed through time by natural selection, progressing from simple forms to more modern forms in the Pleistocene, suggested that all species extinct and living are parts of a single Tree of Life. The ToL records relationships between organisms, and the tree itself is rooted in a single ancestral species. Fossil evidence is fundamental to understanding evolution, based on the

taxonomy and classification of fossil organisms, and their distribution in time and space. The ToL is, like any natural tree, composed of roots, a trunk, and branches. The dividing of the branches simulates speciation events. Speciation generally involves the splitting of a population into two perhaps by a physical or ecological barrier. The most common mechanism is that of allopatric speciation with populations normally split by a geographic barrier and isolated populations, perhaps stranded on islands form the the basis of the founder effect (MacArthur and Wilson 1967), associated with rapid and unusual evolution.

Two modes of speciation remain under debate (Fig. 4). Phyletic gradualism is characterized by sloping stems and branches, where speciation

**Paleontology, Fig. 4** Two models of speciation. **a**, Phyletic gradualism and **b**, punctuated equilibria

takes place along lineages. On the other hand, punctuated equilibrium posits that lineages are in stasis but periodically speciation occurs as a rapid jump, indicated as lateral shift. There have been a number of tests of these hypotheses using fossil data. Because demonstration of the these models requires evolution within a single geological section, free from gaps and migrations of species in

and out of the area, punctuated equilibrium can be difficult to prove and easy to falsify.

Fossil data have been critical in understanding the relationships between organisms on the Tree of Life. Using cladistics methodologies based on morphology, there are now many phylogenies or trees available for most animal and plant groups, constructed using a range of computer software.

Other attributes can be mapped onto trees such as the paleobiogeographic distributions, age-range data, and the paleoecologies of organisms on parts of the tree. More recently trees have been reconstructed using molecular data or phylogenomics, and a molecular clock can be applied based on understanding the rates of change of particular proteins such as hemoglobin. Fundamental, however, is the calibration of such trees, and this can only be achieved by accurately dating the first occurrence of fossil members of those investigated clades (Donoghue and Benton 2007).

## Diversification and Extinction

Life has diversified from a single species deep in the Precambrian to between 2 and 20 million species today, a massive increase in species richness over some 4 billion years of Earth history. It is uncertain if there is a distinct pattern to this diversification; only a relative small number of species have ever been preserved; moreover estimates suggest that about 99% of organisms that ever existed are now extinct. Various models have been applied to this diversification, linear, logistic, and exponential, but there is no consensus. Rather

organisms have diversified through deep time, finding ways to adapt to new ecospace, changing conditions, and environments and balancing speciation with extinction to generate a highly irregular pattern.

Analysis of the fossil record demonstrates there were five major intervals of mass extinction, when over 30% of organisms went extinct during each event (Fig. 5). The animals and plants included a broad range of ecologies, attached to many different habitats, and the extinctions were global over a very short interval of time. The “big five,” the End Ordovician, Late Devonian, Permian-Triassic, End Triassic, and the Cretaceous-Paleogene, marked the turning points in the history of life but also set life off in different directions (Bambach 2006). For example, at the end of the Cretaceous, dinosaurs (excluding the birds) disappeared, but as life recovered the mammals gained diversity and dominance on land. Many causes have been advanced for the big five, each has its own peculiarities. The End Ordovician is associated with an ice age; the Late Devonian witnessed major cooling and anoxia; the Permian-Triassic (by far the most severe with the extirpation of some 95% of species) is associated with a run-away greenhouse; the End Triassic with anoxia and global warming; and an asteroid

**Paleontology, Fig. 5** The diversification of (a) marine life and (b) life on land. Life changed forever across the largest extinction of them all, at the Permian-Triassic boundary; the Paleozoic faunas (green and pink) were

replaced by “Modern” animals and plants (blue and beige). (From various sources summarized in Benton and Harper 2020)

impact (evidenced by an iridium anomaly, shocked quartz, melted glass, and a crater) is implicated in the End Cretaceous event (Hallam and Wignall 1997). The fossil record allows us to pinpoint these intervals of catastrophic change but also permits estimates of the rates of extinction in deep time, which habitats are most prone and which organisms are the most resilient. These data may help predict current extinctions and their consequences during what many term the “sixth extinction” with reported extinctions of amphibians, birds, and mammals far exceeding expected background levels.

## Paleoecology

An exciting part of paleontology is the ability to reconstruct the life modes of ancient organisms and their communities. These form two distinct avenues of study: autecology, the ecology of a single organism, and synecology, the investigation of associations or communities of organisms and their relationships to the environment (Brenchley and Harper 1998).

Autecology focuses on the form and function of organisms. There are three main lines of evidence: functional morphology (biomechanics), comparisons with modern analogues, and geological evidence. The functional morphology of an organism may be investigated through the use of biomechanical modelling, with real models consisting of man-made materials or computer simulations. Simple models can, for example, be constructed to understand how dinosaurs walked and ran, how brachiopod shells opened and closed, and how carnivorous reptiles chewed flesh. Comparisons with modern analogues is usually simple if there is a living group with which to compare. The biomechanics and function of limbs were probably similar between those of the fossil horse *Hyracotherium* from the Eocene and those of the genus *Equus*, today. Similarly, a Cambrian brachiopod may have functioned much the same as its modern counterparts. Those without obviously similar descendants such as the dinosaurs might be better compared with analogous though unrelated animals, such as elephants. Finally, the

environmental context is often key: dinosaurs and mammals often occur in sandstones associated with river systems, whereas graptolites are identified with dark mudstones and shales, testifying to deep-water marine environments. Associated biotas provide clues as do trace fossils, the preserved remains of animal and plant behavior, such as burrows, trails, and trackways.

Synecology involves community paleoecology, describing and analyzing the composition and structure of paleocommunities, how species related to each other and the environment and combined together to form food webs (Brenchley and Harper 1998). Most studies commence with intensive, usually bulk sampling of a biota, the careful identification and counts of the absolute abundance of each species and analysis, first using rarefaction curves to test sample size and then measures of diversity, dominance, and evenness to characterize the community. Graphic reconstruction such as those for the Jurassic Period can depict life on land and in the sea based on these data (see Benton and Harper 2020). Jurassic Park is no longer a sense of wonder but a testable hypothesis framed by the collection and analysis of fossils from different ancient environments (Fig. 6).

Relationships between organisms and their environment can be recorded for modern ecosystems by direct observation. For obvious reasons this is simply not possible for fossil organisms. Nevertheless bite marks and borings occur on and in bones and shells, the remains of animals and plants occur in coprolites (animal fossil feces), and increasingly gut contents can be analyzed, demonstrating predator-prey relationships. Commonly the relationship is less aggressive, and commensalism in the form of encrusting organisms such as bryozoans, corals, and serpulite worms on shells is relatively common in the fossil record.

## Biostratigraphy

Fossil organisms have evolved and preserved their temporal ranges in the geological record. The average range of a species is 5 myr; thus fossil-based successions are uniquely useful in

**Paleontology, Fig. 6** Jurassic Park and seas reimagining ancient environments in the early Jurassic on (a) sand, (b) muddy sand, and (c) associated with bitumen; in the late

Jurassic on (d) mud, (e) a reef, and (f) a lagoon. (From McKerrow 1978, modified in Benton and Harper 2020)

correlating geological strata. If, for example, a species of graptolite occurs at a particular level in black shales in Scotland, when found in Central Australia, perhaps in a sandstone, nevertheless the strata are of the same age. Characteristic fossils are typical of given intervals of time; for example, graptolites evolved rapidly during the Ordovician and Silurian, corals are commonly associated with the Carboniferous, whereas ammonites had their acme in Mesozoic strata. These fossil successions form the basis of biozones, the key operational units of biostratigraphy, and thus a stratigraphy can be established based on sequences of evolving organisms.

William Smith had already recognized the use of fossils as a proxy for geological time in the early 1800s as he accumulated data for the first geological map published in 1815, a survey of the geology of England and Wales. Thus, along his transect from northwest Wales to Thames Estuary, the older Cambrian rocks of North Wales were characterized by trilobites, the Carboniferous rocks typified by plants and the younger Neogene sediments of the London Basin, locally packed with mollusk shells and mammal bones. On this basis, British, French, and German geologists, between 1790 and 1840, scrambled to divide geological time each naming periods or systems with distinctive fossils and strata. These pieces of geological time were assembled in order, with the Cambrian at the base and the Tertiary (Paleogene and Neogene) at the top. This provided a very crude way of correlating rocks, but scientists needed much more precision and finer time zones for accurate correlation.

In order to correlate geological strata more precisely, fossils are normally organized into assemblage or range zones, based on the work of Albert Oppel (1831–1865). Oppel's methodology was modern and rigorous and formed the basis for correlation. His zones were lithological units with unique associations of species and were aligned with stages, which could be recognized regionally and occasionally, globally. These units functioned well, but modern practice would define each stage and zone in terms of a measured range in a rock succession (Doyle 2001). A number of more sophisticated numerical methods are now

available to accurately compare and correlate two or more geological sections based on zonal ranges (Hammer and Harper 2006).

Some organisms are better than others as zonal fossils; those which are widespread are easily preserved and evolve rapidly. And different fossils characterize best particular time intervals (Fig. 7). Correlation, primarily by fossils, allows us to differentiate local events in a single marine basin of a river system from those truly global events such as mass extinctions.

## Paleobiogeography

Tectonic plates have moved throughout geological time, associated with island arcs and microcontinents, and so too have the positions, shapes, and sizes of biotic provinces. Fundamental evidence for continental drift was provided by not only the fit of the African and South American continents but also the continuity of faunas and floras across these and the continents of Australia and Antarctica (Fig. 8). It was not until the paradigm shift of the 1960s with the theory of plate tectonics that a realistic explanation for the movement of continents, that is, continental drift, could be adequately explained.

Fossil data have been essential in reconstructing the past positions of the continents and the oceans, barriers on land and in the sea, and migrational routes and biodiversity hot spots (Benton and Harper 2020 for summary and sources). Climate has changed dramatically through time. Many animals and plants are climatically sensitive; their distributions today commonly track altitude, latitude, or the movement of cold and warm air and water currents; these properties can further aid paleogeographic reconstructions. The Ediacara biota of the Late Precambrian already demonstrated some provinciality. The Early Paleozoic animal communities were clearly structured into provinces particularly within the brachiopods and trilobites together with the graptolites and mapped out the extent, margins, and positions of ancient continents (Harper and Servais 2013). By the Carboniferous and Permian, life on land was well established, the

**Paleontology, Fig. 7** Ranges of key fossil groups used in biostratigraphic correlation of different parts of the geological timescale. (From Benton and Harper 2020)

continents dispersed, and ancient floral provinces were clearly identifiable; the *Glossopteris* floral province is one of the best known, linking the southern continents. During the Mesozoic provincial patterns in the oceans were relatively simple, with marine life organized into Boreal (high-latitude) and Tethyan (low-latitude) provinces. On land, more complex ecosystems and bioregionalization patterns were provided by the rise of the dinosaurs during the Triassic and the appearance of flowering plants in the Cretaceous. In the Paleogene and Neogene, the configuration of the continents approached those of the present day, and our map of the provinces converged on modern biotic regions.

**Fossils in Mountain Belts**

The stratigraphy of mountains is fundamental to understanding global tectonic processes, and their distinctive faunas and floras had key roles to play, commonly as isolated island environments, in the

evolution of life on Earth (Harper 1998). Fossils have proven immensely useful in dating sedimentary rocks in mountain belts, assessing their provenance and the finite strain recorded in the rocks. “One bad fossil is worth a good working hypothesis.” This key statement from the eminent Alpine geologist Rudolf Trümpy reflected the fact that the discovery of a single fossil can literally turn a mountain belt on its head. Fossils in mountain belts are, however, generally rare, metamorphosed, and tectonized. Nevertheless when identified, fossil material can pinpoint the age and provenance of rock units. For example, large-scale mass horizontal movements of slabs of crust, or thrust sheets, in the Swiss Alps, Northwest Scottish Highlands, and the Scandinavian Caledonian mountains were detected over a century ago by the discoveries and utility of fossiliferous successions.

Both Steno and Darwin, in their respective studies during the late 1600s and early 1800s in the Apennines and the Andes, recognized shells on the tops of mountains and speculated about

**Paleontology, Fig. 8** Carboniferous and Permian distributions of plant and reptiles linking the southern continents; this fit suggested to Alfred Wegener that

subsequently the continents drifted apart to their present positions today. (From Benton and Harper 2020)

large vertical movements in the Earth's crust. During the early ascents of Mount Everest, rock samples collected from at and near the summit were submitted for analysis. Fossil data initially suggested a range of ages. During the 1960s expeditions to the Everest Ranges focused on dates within the Ordovician based on shelly faunas such as brachiopods and cephalopods, confirmed more recently by conodonts (Stouge et al. 2020). The limestones capping Everest were indeed Middle Ordovician in age, and the summit of the roof of the world lay within warm tropical seas, rich in animal life, some 465 million years ago (Fig. 9). The region was uplifted and amalgamated into the Himalayan mountain belt, when India collided with the rest of Asia 55 million years ago.

Paleontological data have predicted and evidenced the existence and positions of ancient

oceans. The present day Atlantic Ocean separates Europe from North America, but did the Atlantic Ocean open, close, and reopen (Wilson 1966)? Examination of the brachiopods and trilobites within the Caledonian mountain belt suggests a suture existed within the belt, stretching from the north of Norway to Florida, indicating that during the Early Paleozoic an ancient ocean separated Europe from North America. Preserved in the ancient Caledonian Orogen are the remains of oceanic crust but, more significantly, islands which contained locally diverse fossil faunas contrasting with those of the continental margins of Europe and North America. The roles of such islands as ancient analogues of the Galapagos Islands today have been hypothesized.

Rates of geological events and processes have been constrained by paleontological data. The

**Paleontology, Fig. 9** The roof of the world. The rock formations displayed on the north face of Everest indicating that fossils from the summit provide crucial evidence to

date these rocks and indicate their origin before uplift in shallow-water tropical seas around an ancient equator. (Photo of Everest from Wikipedia)

Banda Arcs form a Neogene and Quaternary tectonic belt along the northern continental margin of Australia. Detailed biostratigraphy, based on foraminiferan microfossils, indicates the start and termination of folding and the age of emplacement of the thrust sheets, their imbrication, and the timing of the uplift of the tectonic belt as a whole. The thrust sheets travelled some 50 km southwards during 4–5 million years, to overthrust the Australian plate. Estimates based on the foraminiferan zonal stratigraphy suggest the thrusts were emplaced at between 6.25 and 12.5 cm per year, while the belt was uplifted at rates of about 1.5 cm per year.

Fossils thus can help reconstruct complex plate movements, but they can also quantify the amount of strain in rocks (see Benton and Harper 2020). Many fossils, originally symmetrical, are deformed in tectonic belts, the amount of strain in the rocks can be assessed and the fossil returned to their normal shape by the use of simple drawing software. Moreover, since some fossils change

color during metamorphism, the thermal maturation of strata can be estimated. Conodonts, for example, are useful thermal indicators, changing color from light amber through gray, black, and white eventually becoming translucent at temperatures of about 600 °C. Other fossils such as acritarchs, graptolites, and plant materials (vitrinite) also display color changes. In addition, paleotemperatures are commercially useful, predicting the so-called oil and gas window, where reservoirs hold extractable hydrocarbons.

## Conclusion

Almost certainly unique to ourselves, *Homo sapiens*, is consciousness, and part of that property is a curiosity about our origins, where we came from, and where we fit into the history of a unique planet and its biosphere that is over a billion years old. Humans can think about our existence, its past and its present, and plan for our

future. That brings knowledge but also a massive responsibility.

## Panbanisha and Panzee

Karen Brakke

Spelman College, Atlanta, GA, USA

## Synonyms

### Panpanzee

Bonobo Panbanisha (*Pan paniscus*, November 1985 – November 2012) and chimpanzee Panpanzee (known as Panzee; *Pan troglodytes*: December 1985 – February 2014) were apes co-reared from early infancy by E. Sue Savage-Rumbaugh and colleagues at the Language Research Center (LRC) in Atlanta, GA. They were reared in a language-rich environment by a stable team of human caregivers in order to illuminate the nature and extent of species differences and environmental influences on the development of language skills in the nonhuman primates most closely related to *Homo sapiens*. Their primary means of symbolic communication with their caregivers was through touching “lexigrams,” which are arbitrary visual symbols that are equivalent to printed words. Different lexigrams denoted types of foods, objects, individuals’ names, locations, actions, adjectives, and other concepts (e.g., yes, no) that were prevalent in the

young apes' world. Panbanisha and Panzee had access to about 256 lexigrams during their co-rearing period.

Chimpanzees and bonobos are closely-related species; both are believed to have diverged from the human lineage approximately six million years ago and, therefore, serve as our closest evolutionary relatives as well. Prior research with chimpanzees Lana, Sherman, and Austin and bonobos Kanzi and Mulika had resulted in a confound between species, age of initial symbol learning, and symbol-teaching strategies that made it difficult to draw conclusions about non-human primates' learning of language skills. Specifically, the chimpanzees had been enrolled in the language research projects after they were 1 year of age and had been taught to use and respond to lexigram symbols primarily through trial-based reinforcement learning. The bonobos had been exposed to lexigrams and rich spoken English earlier in infancy and had learned symbol use through a more naturalistic enculturated rearing process in which human caregivers used speech and symbols to communicate with the bonobos throughout daily routines, much as is done in human families. The bonobos demonstrated more extensive and flexible symbol use than did the chimpanzees, and surprisingly, also exhibited substantial comprehension of spoken English. However, it was not clear whether these disparities represented true species differences, or were facilitated by different rearing environments and practices. Detailed information on the projects with these chimpanzees and bonobos can be found in Rumbaugh (1977: Lana), Savage-Rumbaugh (1986: Sherman & Austin), and Savage-Rumbaugh, Murphy, Sevcik, Brakke, Williams, and Rumbaugh, (1993: Kanzi).

Panbanisha and Panzee were reared together from the age of a few weeks until they were approximately 4 years of age, when Panzee was moved to the chimpanzee colony at the LRC. During their early years, Panbanisha and Panzee were immersed in an environment designed to facilitate comprehension and production of symbolic communication. The LRC laboratory facility in which they were raised included several ape-safe rooms with kitchen, bath, sleeping, and play

areas as well as over 50 acres of woods with countless trees to climb and several trails leading to sites baited daily with a variety of foods. A small team of caregivers accompanied the young apes throughout the day, using English and lexigram communication as they participated in daily routines of care, play, feeding (both outdoor foraging and indoor food preparation), household chores, and bedtime. Most days also included some type of assessment session or quiet time during which the young apes were expected to sit calmly and focus on the task at hand. Thus, their first years were structurally and linguistically as similar as possible to those experienced by young human children given that Panbanisha and Panzee were not allowed to leave laboratory property.

Caregivers recorded all instances of lexigram use and demonstrations of English or lexigram comprehension and production during daily activities and also conducted experimentally-controlled studies of English word comprehension. The resulting data indicated that both Panbanisha and Panzee understood several spoken English words and visual lexigram symbols and used symbols appropriately to communicate with their caregivers. The bonobo, however, began using lexigrams at an earlier age; had a larger, more flexible vocabulary; and appeared to be less context-dependent when interpreting complex utterances. Between 3 and 4 years of age, Panbanisha's receptive vocabulary, tested under controlled conditions matching English words to lexigram symbols, included approximately 186 words, while Panzee's included around 97 (Brakke and Savage-Rumbaugh 1995). Panbanisha's productive vocabulary, including lexigram symbols used spontaneously at least once per month, included approximately 140 symbols; Panzee's included approximately 90 symbols (Brakke and Savage-Rumbaugh 1996).

Later analyses of Panbanisha's and Panzee's symbol comprehension and use supported these early findings of vocabulary size with some growth over time (e.g., Beran and Heimbauer 2015), and also suggested that both apes combined symbols in ordered ways suggestive of a primitive grammar or "protogrammar"

(e.g., Lyn et al. 2011). Notably, both apes engaged in conversational turn-taking with their caregivers in ways that let them negotiate their daily life in much the same way as young human children. Panbanisha's performance across many linguistic measures corroborated that of bonobo Kanzi (See Savage-Rumbaugh et al. 1993) and provided insight into the possible foundations of early human language acquisition as well. Panzee – although not as adept with symbolic communication as were the bonobos – was the first, and to date only, chimpanzee to demonstrate extensive English speech comprehension under experimentally controlled conditions and to engage in symbolic communication using lexigrams without repetitive trial-based training.

Panbanisha's and Panzee's skills with English comprehension and use of communicative symbols also facilitated inquiry into other cognitive skills and interactions. Both apes demonstrated the ability to plan and navigate computer-mediated mazes using a joystick and to manipulate sets of objects in ways that reflected an underlying logic. In addition, after relocating to the chimpanzee colony, Panzee also participated in Michael Beran's (e.g., Beran and Evans 2012; Beran et al. 2013) and others' studies of chimpanzee cognition along with Sherman, Austin, Lana, and Mercury. In these studies, Panzee demonstrated skill with enumeration and quantification, self-control, prospective memory, and several other cognitive skills.

In a notable series of studies on spatial memory led by Charles Menzel (e.g., Sayers and Menzel 2012), Panzee regularly and accurately used lexigrams and gestures to communicate to experimentally naive caregivers that specific foods or other items had been hidden earlier by another person in the woods around her enclosure. She then used gestures, eye gaze, and vocalizations to remotely direct the caregiver to the buried cache. In extensions of this work, Panzee rank-ordered her preference among multiple hidden caches based on food type, food quantity, and ease of access in a way that related to the energy- and time-efficiency of obtaining the food (Sayers and Menzel 2012). Panzee lived with the other

chimpanzees at the Language Research Center until her death in February 2014.

Panbanisha was enrolled in the bonobo Species Survival Plan and gave birth to sons Nyota and Nathan. She and her offspring moved in the year 2005 with Kanzi and the other LRC bonobos to the Great Ape Trust of Iowa in Des Moines (now known as the Ape Cognition and Conservation Initiative). In November 2012, Panbanisha died after a brief illness.

The research with Panbanisha and Panzee has contributed to our understanding of the evolution of human language and cognition in several ways. In both species of *Pan* – as represented by Panbanisha and Panzee – many of the cognitive and social bases of language skills appear to be present at least to some degree, particularly in human-enculturated environments that support the development of these capacities. The work with these and other apes, through extension to our own species, also highlights the remarkable neural specializations in humans that have resulted in the capacity to elaborate on these higher cognitive and communicative skills as well as to leverage culturally-transmitted knowledge passed along over thousands of generations to yield powerful systems of cognition and language.

## Pangolin

Wouter Schaake  
University of Utrecht (Alumnus), Utrecht,  
The Netherlands

## Synonyms

*Pholidota*; *Scaly anteater*

## Definition

The pangolin family is comprised of a variety of scaly, armored terrestrial mammals that in appearance somewhat resemble armadillos and anteaters. Depending on the exact species, pangolin size ranges between that of a rabbit and a medium-sized dog. Due to similarities in morphology and diet, pangolins may be referred to as “scaly anteaters.”

## Introduction

The order of Pholidota, to which the pangolin belongs, contains only a single extant family of animals. This family, Manidae, in turn contains the three genera *Manis*, *Smutsia*, and *Phataginus*, to which the eight currently living species belong (Gaudin et al. 2009). Besides being the only extant species within their lineage, pangolins feature a full-body scaly keratinous armor that is unique among mammals. Functionally similar to the armored bands of the armadillo, the pangolin’s scaly armor makes it relatively impervious to predator attacks when curled into a ball, and the scales’ sharp edges additionally deter attempts to circumvent this defensive mechanism (Ganguly 2013; Robinson 1983; Wilson 1994). Correspondingly, the name “pangolin” derives from the Malay “Pengguling” which roughly translates to “rolling,” as per the animal’s defensive mechanism (Lexico 2019).

## Behavior and Ecology

Pangolins are found in the southern regions of Asia as well as in sub-Saharan Africa and prefer a range of predominantly vegetated habitats where their main dietary components of ants and termites are abundant (Choo et al. 2016; Gaudin et al. 2009; Robinson 1983; Save Pangolins 2019a; Wilson 1994). Apart from their characteristic scaly armor, pangolins may use a foul-smelling odor secreted from their anal glands as a further defensive measure (Ganguly 2013; Wilson 1994). Pangolins boast a variety of

specialist adaptations that make them well-equipped for their particular ecological niche. Their powerful clawed front legs are ideally suited for burrowing or climbing trees, as well as breaking open ant hills and termite mounds so as to reach their prey items (Ganguly 2013; Robinson 1983; Wilson 1994). Tree-dwelling species tend to use their prehensile tail to add to their climbing prowess (Ganguly 2013; Robinson 1983). As all but one species are nocturnal, pangolins rely on their acute sense of smell to pinpoint food items (Ganguly 2013; Wilson 1994). Indeed, genetic research has shown that both the Asian and African pangolin varieties bear genetic markers associated with a highly developed sense of smell (Choo et al. 2016). Their extremely elongated and extendable tongue is used to lap up insects and is unique among mammals in that it extends into the abdominal cavity (Chan 1995; Ganguly 2013; Wilson 1994). In order to prevent insects crawling into their facial orifices, pangolins use a set of membranes to protect their eyes and are able to close off their nostrils and ears during foraging (Ganguly 2013; Wilson 1994), making them well-equipped to deal with the challenge of eating ants and termites.

## Lineage and Subspecies

Although both extant and extinct species of pangolin fall within the order of ‘*Pholidota*’, the detailed resolution of their phylogeny has long remained a point of dispute. Part of the issue in resolving the pangolin family tree lies in the animals’ morphology and ecology. The lack of teeth, preference for vegetated environments, and low population densities characteristic for *Pholidota* are believed to have resulted in a relatively poor fossil record, making detailed morphological studies challenging (Gaudin et al. 2009). Currently, the most accurate subdivision of extant species appears to be across three separate genera: ‘*Manis*’, ‘*Phataginus*’, and ‘*Smutsia*’. Within this division, the four extant Asian species are classified as ‘*Manis*’ and include the “Indian pangolin” (*M. crassicaudata*), “Chinese pangolin” (*M. pentadactyla*), “Sunda pangolin” (*M. javanica*), and “Philippine pangolin” (*M. culionensis*). The

four extant African species are divided between the *Phataginus* and *Smutsia* genera, the first of which contains the predominantly arboreal “tree pangolin” (*P. tricuspis*) and “African black-bellied pangolin” (*P. tetradactyla*), while the latter contains the more terrestrial “giant pangolin” (*S. gigantea*) and “ground pangolin” (*S. temminckii*) (Gaudin et al. 2009).

## Conservation Status

Although the pangolin’s natural predators do not extend beyond leopards and pythons (Wilson 1994), all species are under heavy threat from human activity. In fact, pangolin varieties are now the most trafficked mammals in the world due to the value of their meat and scales in Chinese traditional medicine. As such, all pangolin species are currently experiencing population collapses due to poaching activity (Aisher 2016; Save Pangolins 2019b). Because a single pangolin is estimated to consume up to 70 million individual insects per year, they play a vital role in the control of social insect populations, thus balancing the ecosystems they live in (Durojaye and Olufemi 2015; Save Pangolins 2019a).

## Concluding Remarks

Due to their many specialist adaptations, these animals make for a somewhat strange, yet fascinating group. Sadly, the pangolin’s intrinsic value, as well as its role in maintaining social insect populations within ecosystems, is currently under heavy threat from poaching and trafficking. In order to ensure the future of pangolins outside of captivity, more concerted and global conservation measures must be attempted (Durojaye and Olufemi 2015; Save Pangolins 2019b).

## Definition

Parahippocampal cortex, termed postrhinal cortex in the rodent brain, is a region in the medial temporal lobe that is involved in processing visuo-spatial and contextual information in the service of episodic memory or memory for the events of our daily lives.

## Introduction

More than half a century ago, Scoville and Milner were the first to determine the importance of the hippocampus in memory as a result of involvement in the influential case of HM, the famous amnesiac patient whom we now know as Henry Molaison. Over the next few decades, it became apparent that memory processes were also supported by distinct cortical areas surrounding the hippocampus. Decades of research have shown that these parahippocampal structures are not merely conduits of information for the hippocampus, but that they have specific functions with regard to memory. It is now widely accepted that

the interaction between the hippocampus and these surrounding areas is necessary for associative learning and episodic memory.

The hippocampal memory system, also called the medial temporal lobe memory system, includes the hippocampal formation and the parahippocampal region. The hippocampal formation includes the dentate gyrus, the hippocampus proper (fields CA1, CA2, and CA3), and the subiculum. The parahippocampal region comprises the perirhinal, parahippocampal (PHC), and entorhinal cortices, as well as the presubiculum and parasubiculum. The PHC is located on the ventral surface of the temporal lobe bordered rostrally by the perirhinal cortex and entorhinal cortex and laterally by area temporal cortex (Suzuki and Amaral 2003). The situation is similar in the rodent brain, except that the region homologous to the PHC is termed the postrhinal cortex (POR). In the rat and mouse, Burwell and colleagues defined the POR as the area caudal to the perirhinal cortex and dorsal to the rhinal sulcus (Beaudin et al. 2013; Burwell 2001). The rodent POR wraps obliquely around the caudal pole of the brain and is bordered dorsally by the temporal association cortex and ventrally by the EC. The POR is subdivided into dorsal and ventral subregions. Likewise, the monkey PHC is composed of two subregions, areas TH and TF.

In the primate brain, it is important to realize that the word “parahippocampal” is used in four different anatomical and functional phrases: the “parahippocampal region,” the “parahippocampal cortex,” the “parahippocampal gyrus,” and the “parahippocampal place area.” Unfortunately, these terms are often used interchangeably, especially in the functional imaging literature. Again, for clarification, the parahippocampal regions include five anatomical structures, one of which is the PHC. The parahippocampal gyrus includes parts, but not all of the perirhinal cortex, the entorhinal cortex, and the PHC. The parahippocampal place area is not an anatomical structure, but rather is a region that is functionally defined in human imaging studies and varies across individuals. In rodents, this ambiguous nomenclature is avoided as the area homologous to the PHC is termed the POR. The rodent brain is

smooth, and so there are few sulci and no gyri. Thus, in rodents “parahippocampal” is used only to designate the parahippocampal region.

## Structure

Comparisons of the hippocampal memory system across humans, monkeys, rats, and mice show strong structural similarities. For example, the perirhinal, PHC/POR, and entorhinal cortices are associated with the caudal portion of the rhinal sulcus and show similar adjacencies in rodents and primates (Fig. 1). Neuroanatomical studies show substantial connectional homology of the PHC and POR across primates and rodents for both hippocampal, cortical, and subcortical structures. As might be expected given the role in memory, PHC/POR is connected with hippocampus both directly and via the entorhinal cortex. PHC/POR has direct and reciprocal connections with hippocampal field CA1 and the subiculum (Agster and Burwell 2013; Suzuki and Amaral 1990). Indirect projections are through EC to the dentate gyrus and hippocampal field CA3. The PHC/POR is strongly interconnected with the perirhinal cortex, although the inputs from the perirhinal cortex may be stronger than the reciprocal connections.

Both PHC and POR receive substantial visual and spatial input, which supports their role in visuospatial functions. For both PHC and POR, this input arises predominantly from visual association, retrosplenial, and posterior parietal cortices. The outputs are also similar. In the PHC, both TF and TH largely receive input from visual areas. TH, however, also receives input from auditory regions. The situation is similar for the POR in that both subdivisions receive input from visual and visuospatial areas, but the ventral subdivision also receives auditory input. The return connections are also strong to visual and visuospatial areas. Additionally, both areas have strong connections with the thalamic pulvinar in primates and the homologous lateral posterior nucleus in rodents (Agster et al. 2016; Baleyrier and Mauguier 1985). Notably, the pulvinar is implicated in visuospatial attention. Taken together,

**Parahippocampal Cortex (PHC), Fig. 1** Comparative views of the hippocampal memory system. Shown are surface views for the in the human, monkey, and rodent brains (a-c). The upper panel shows a lateral view of the hippocampal formation (HF), as well as parahippocampal structures including the perirhinal cortex (PER), parahippocampal/posrhinal cortex (PHC/POR), and entorhinal cortex (EC). The lower panel shows flattened maps of these regions in the human, monkey, and rodent (d-f). These

unfolded maps show PER areas 35 and 36, PHC subregions TH and TF in the monkey, as well as the lateral and medial entorhinal areas (LEA and MEA) in the rodent. Although not shown here, the primate EC is also subdivided into lateral and medial subdivisions. This figure was adapted from Burwell and Agster (2008) with permission (Elsevier, Inc.). Abbreviations: *cs*, collateral sulcus; *rs*, rhinal sulcus; *D/L*, dorsal/lateral; *R*, rostral; *C*, caudal; *V/M*, ventral/medial; *S*, septal; *T*, temporal

this pattern of connections suggests roles for POR/PHC in visual information processing and visuospatial attention.

## Function

Current views of medial temporal lobe function tend to emphasize that spatial and non-spatial information reach the hippocampus through segregated parahippocampal pathways. Spatial and contextual information is conveyed by the PHC/POR and the medial entorhinal area, and non-spatial information is conveyed by the perirhinal cortex and the lateral entorhinal area. There is, however, considerable cross-talk between these pathways at multiple levels (Fig. 2). Of importance, here, the perirhinal cortex and PHC/POR are directly connected.

Substantial evidence indicates the PHC/POR is involved in some, but not all, spatial functions. Rats with POR damage perform normally on most navigation tasks, but they are impaired on tasks that require processing of contextual information, that is, the local environmental context. This is consistent with findings of human imaging studies in which the PHC was shown to be involved in processing information about the environment, or context, but not in navigation (Epstein et al. 1999). Human imaging studies also implicate the PHC in a variety of higher-order cognitive functions including visual scene processing, binding of objects and contexts, and episodic memory (Aminoff et al. 2013). In addition, activity in the PHC increases when individuals are presented with objects that have strong contextual associations, regardless of whether the associations are spatial or non-spatial.

**Parahippocampal Cortex (PHC), Fig. 2** Pathways for nonspatial and spatial information into the hippocampal memory system. The nonspatial pathway is on the left and the spatial pathway is on the right. Sensory and prefrontal (PFC) information arrive in the perirhinal cortex (PER) and are used to identify individual items and objects. PER projects directly to the hippocampus and indirectly through the lateral entorhinal area (LEA). LEA likely uses this information to represent how objects are arranged in space possibly for the purposes of navigation. Visual and spatial information arrive in the parahippocampal/

postrhinal cortex (PHC/POR) which projects directly to the hippocampus and indirectly through the medial entorhinal area (MEA). The MEA likely uses this information for representing Euclidian or metric space. The PER also projects directly to the PHC/POR, likely providing object information so that the PHC/POR can represent the spatial layout of the objects and patterns that define the current environmental context. Spatial/contextual and nonspatial information are combined in the hippocampus for the purposes of associative learning and episodic memory

One question of interest is why the PHC/POR connections with perirhinal cortex are so robust. Abundant evidence indicates a role for perirhinal cortex in recognition and identification of individual objects. If one considers what comprises an environmental context, it becomes obvious that information about objects would be important. Most contexts are not empty rooms or bare environments, but are filled with objects and items that define the space. One interpretation that accommodates available evidence is that the PHC/POR encodes the physical features of environmental contexts including place, position of objects, and non-spatial feature information, for example, the furniture in a room and the pattern of the floor. Interestingly, neurons in the POR signal the location of objects in particular places (Furtak et al. 2012). If PHC/POR is representing the spatial layout of the objects and patterns in a particular environment, such

object location conjunctive coding would be expected.

## Conclusion

The conventional view of parahippocampal-hippocampal circuitry proposes that visuospatial information from multiple cortical regions converges in the PHC/POR on its way to the hippocampus and that nonspatial information is transmitted through the perirhinal cortex. This concept of parallel-processing streams is widely accepted; however, there is evidence that the PHC/POR is not simply accruing and transmitting spatial information. A modified view is that the PHC/POR relies on object information from the perirhinal cortex for the representation, identification, and discrimination of specific environmental contexts. Accordingly, the perirhinal cortex

supplies object information to the PHC/POR for representation of context and to the hippocampus for associative learning and episodic memory. Taken together, available evidence suggests that the POR/PHC encodes representations of specific contexts, monitors the current context, and updates these representations when a change occurs. This information would then be transmitted to the hippocampus for forming episodic memories and for associative learning.

## Parallel Distributed Processing

Ivan Vankov

Institute of Neurobiology, Bulgarian Academy of Sciences, Sofia, Bulgaria

## Introduction

The modern understanding of biological cognition has been heavily influenced by the computer metaphor or the idea that cognitive processes can be construed in terms of information processing. This idea was conceived in the early 1950s of the twentieth century when it was realized that the inventory of newly discovered digital computers provides a powerful framework for understanding the mind. Cognitive scientists readily grasped the idea that performance in tasks such as problem solving or visual object recognition can be described by drafting an algorithm of a series of distinct computations operating on well-defined data structures. The advantage of this approach was that it allowed the development of formal theories of cognition and the generation of testable predictions about behavior. However, it was soon realized that there are aspects of cognition which are hard to be accounted for in this manner. For example, the high granularity of the computer-inspired operations and data structures made it difficult to explain how a living organism gradually acquires new knowledge and adapts to the environment.

Discoveries in neuroscience (Hubel and Wiesel 1959; Hebb, 1961) as well as the pivotal work of McCulloch and Pitts (1943) on

mathematical modeling of the neural system provided an alternative way to formally account for cognition. In this framework, known as neural network modeling or connectionism, the incoming signal is processed by the simultaneous activation of a number of interconnected uniform computational units, artificial neurons, each of which performs a very simple task, such as the linear transformation of a number. Connectionism, therefore, assumes that any cognitive computation can be expressed as propagation of activation in a neural network, and the task of the modeler is only to find the right neural network architecture which can support a given task.

The first neural network models, such as the perceptron (Rosenblatt, 1957), consisting of just a few neurons, initially showed promising results, but it was soon demonstrated that such simple models have severe limitations (Minsky & Papert, 1969). It took about 20 years to overcome the problems and to develop theories and tools which allow researchers to build more complex and scalable neural network models. A turning point was the publication of the parallel distributed processing (PDP) volumes (Rumelhart et al., 1986) which set the foundations of modern connectionist modeling.

## Principles of PDP

A PDP neural-network model consists of a network of units which are usually organized in layers (Fig. 1). At each moment in time, the state of a unit is characterized by its level of activation, given by a real number. The connections between artificial neurons let the activation spread through the network, a process known as *spreading of activation*. The activation values of all units – a vector of real numbers – describe the knowledge currently encoded by the system. The spreading of activation is modulated by the pattern of connectivity – not all units are connected to each other and the strength (or *weight*) of the connections can vary. The level of activation of a given unit is a function (known as *activation function*) of the net amount of activation received by other units and a threshold parameter (a *bias term*) (Fig. 2). One of

**Parallel Distributed Processing, Fig. 1** An artificial neural network unit connected to  $n$  other units ( $k_1 - k_n$ ). The strength of the connection between unit  $k_i$  and  $x$  is indicated by the value of connection weight  $w_{kix}$ . A negative weight would indicate that unit  $k_i$  inhibits  $x$ . Units in hidden layers are usually also connected to a constant source of activation called bias. The effect of bias depends on the weight of the connection to the bias node ( $b_x$ ). Connection weights are considered parameters of the model and their optimal values and subject of learning

$$act(x) = f\left(\sum_{i=1}^n act(k_i)w_{k_ix} + b_x\right)$$

**Parallel Distributed Processing, Fig. 2** Calculating the level of activation of unit  $x$ . The net input to the unit is determined by taking the activation of each unit connected to  $x$  and multiplying it by the corresponding connection weight. The activation function  $f$  is then used to compute the level of activation of  $x$ . Activation functions vary across models but typical choices are s-shaped nonlinear transformations which keep the resulting value capped in a certain interval, such as  $[0, 1]$  or  $[-1, 1]$ . Importantly, the activation functions must be differentiable in order to be able to apply the back-propagation algorithm for finding the optimal values of the network parameters

the breakthroughs of the PDP approach was the introduction of nonlinear activation functions, such as sigmoids.

The operation of a PDP neural network model starts by manually setting the activation levels of some of the units in the “input” layer. The activation is then propagated to the rest of the network. The output of the model is determined by the activation levels of another layer of special units – the “output.” All the other units, which are neither externally activated nor considered an

output of the model, are referred to as “hidden” units. The number and the connectivity of hidden units determine the computational power of the model and is what defines the characteristics of neural network architecture.

There are two main types of PDP neural network architectures (Fig. 3). In feed-forward networks, the activation flows in a single direction and the computation is completed in a single time step. Typical applications of feed-forward networks include modeling tasks such as pattern recognition and classification. Recurrent architectures are time-sensitive and involve circular connectivity meaning that the activation of a unit at a given time may depend on its activation at a previous moment. They are particularly suitable for modeling cognitive processes requiring the capacity to store items in short-term memory, such as language comprehension and planning.

The main reason why the PDP modeling paradigm turned out to be so successful is that it provided a compelling account of learning. Learning in a PDP model can be viewed as finding the optimal values of the model parameters – the connection weights – with respect to a particular objective. The objective is defined by an *error* (or “*loss*”) function which quantifies the discrepancy between the desired and the actual output of the model. This kind of learning is referred to as “supervised” as it assumes that for each input to the model we know what the right output pattern should be. An important moment in the history of neural network modeling was the invention of the back-propagation algorithm for supervised learning which allowed researchers to train models (i.e., to find the optimal values of their connection weights) with varying complexity.

**Parallel Distributed Processing, Fig. 3** A sample feed forward (left) and recurrent (right) PDP model. In the feedforward model, activation flows unidirectionally from the input layer towards the output layer. The levels of activation of the output layer can be computed in just one iteration so there is no notion of time. The recurrent model has circular connectivity within the hidden layer,

and therefore a single input pattern may lead to multiple activation patterns within the hidden layer (and varying outputs) as the activation in the hidden layer is allowed to circulate. Recurrent architectures have much more computational power and are capable of modeling the dynamics of cognitive processes

## PDP as a Theory of Cognition

The PDP approach is not just a collection of modeling tools and formalisms but also a framework for understanding cognition. It imposes constraints on cognitive modeling which extend far beyond technical details.

A central assumption of the PDP approach is that information is processed in parallel, implying that there is no central processor controlling the computation, and it is not possible to pinpoint a set of discrete algorithmic steps which are executed in serial order. Such a view is incompatible with the computer metaphor and pushes theorists to thinking about cognition as a dynamic system rather than a computer program.

The second most important stipulation of the PDP framework is that knowledge representation is *distributed*, suggesting one cannot identify particular neural structures (such as neurons) which are responsible for a given fact or feature. For example, if a neural network model is currently representing a brown domestic cat, you can't figure out what the patterns of activation of individual features such as "brown," "cat," or "domestic" are. According to PDP theorists, distributed representations are essential for enabling generalization – the ability to process novel information – because the representation of novel inputs will always overlap to some extent with existing representations. Other advantages of distributed representations include context-sensitivity (the representation of a cat sitting on a sofa will be very similar but still different from the representation of a cat on a roof) and *graceful degradation*. The latter means that damaging a neural network leads to gradual loss of functionality, just as in aging animals, rather than in abrupt changes. However, the distributed representational format also makes predictions which can be described as problematic. For example, having continuous representations with blurred boundaries is incompatible with the symbolic view of knowledge – the idea that there exist atoms of knowledge which can be combined productively to form new meaning (Dietrich & Markman, 2003; Hummel, 2016).

A prime example of symbolic knowledge is natural language – we can produce and comprehend sentences we've never heard before by processing known words in novel combinations. The question of whether and how PDP can account for symbolic thought was the source of a fierce criticism (Fodor & Pylyshyn, 1988) and is still a hot topic for debate (e.g. Vankov & Bowers, 2020). There are also studies showing that under certain conditions PDP models actually tend to develop highly selective nondistributed representations (Bowers et al. 2014).

One of the most valuable contributions of connectionism to cognitive science is that it lets researchers explain how cognition develops through small incremental steps. For example, Elman, Bates, Johnson, Karmiloff-Smith, Parisi, and Plunkett (1996) argued that connectionist models can provide an empiricist development account of natural language and thus pose a serious challenge to the innateness hypothesis of language acquisition. Moreover, the PDP paradigm, which views learning as a relatively slow process of gradually updating the connection weights, imposes theoretically important constraints on models which adopt it. Many cognitive processes are consistent with this view, for example, learning to make fine-grained perceptual discriminations, detecting statistical regularities, or acquiring motor skills. However, there are also forms of learning which can't be accounted for in this way. For example, humans are capable of fast mapping (Carey & Bartlett, 1978), that is, learning a new category by being exposed to just a few examples. Similar results have also been reported for dogs (Kaminski et al. 2004). Another problem for the PDP account of learning, known as *catastrophic forgetting*, is related to how new information is stored without overwriting the existing knowledge. The problem arises because knowledge in PDP systems is distributed and therefore any change in the connection weights, which is needed to encode new information, will also affect existing representations. In order to address this problem, PDP researchers have proposed the *complimentary learning hypothesis*

(McClelland et al. 1995), which postulates that there exist two distinct systems for learning, one for long-term storage of distributed representations and the other one for quickly encoding new information.

## Biological Plausibility

One of the reasons for the wide adoption of connectionism in the cognitive sciences is that it lets researchers formulate models in a seemingly biologically plausible way. One can easily find biological counterparts of the basic PDP concepts such as a computational unit (nerve cell), level of activation (firing rate), adjustable connection weights (synaptic plasticity), and positive and negative activation flow (excitation and inhibition). The core ideas behind PDP – parallelism and distributing knowledge – are also intact with what we know about biological cognition. However, there are major components of PDP whose physiological plausibility is debatable (e.g. the back-propagation algorithm, Lillicrap et al. 2020) and many important neurobiological mechanisms which are just not accounted for in PDP models (e.g. myelination). It should be kept in mind though that the ultimate goal of cognitive modeling, including connectionism, is to explain cognition. Therefore, the value of PDP models should be judged by how well they account for cognitive phenomena and the theoretical insights they generate and not by how well they mimic the biological neural system. There are other modeling frameworks which explicitly set the goal of describing the operation of real neurons as close as possible (Gerstner & Kistler, 2002), but they are usually not applicable to studying high-level cognitive processes and therefore less popular among cognitive scientists.

## Deep Learning

Connectionism has recently experienced a renewed surge in interest due to the introduction

of a set of artificial neural network models collectively known as *deep learning* (Bengio et al. 2015). Major innovations in deep learning include the ability to efficiently train models with millions of parameters, tens (or even hundreds or thousands) of hidden layers and specific connectivity constraints. Some of the most important deep learning concepts, such as the convolutional neural network (LeCun et al., 1989) and the long-short term memory circuit (Hochreiter & Schmidhuber, 1997), have been proposed much before the deep-learning era, but had not been widely adopted until appropriate hardware and software became available.

Deep learning has achieved spectacular results in various fields of artificial intelligence, surpassing human performance on tasks previously considered to be particularly hard for computers (Silver et al. 2016). It has also affected the study of biological cognition by providing researchers with new tools and letting them complicate and scale up their models. Progress has been made by developing neural network models of cognitive functions which can be applied to real-world data and thus enable direct comparison with human or animal performance (e.g. Abudarham et al. 2019). Indeed, before deep learning, one of the main criticisms of the PDP modeling approach had been that it could only be used to address toy problems. At the same time, deep learning cannot be viewed as a conceptual breakthrough in understanding cognition, as long as it is based on the same fundamental principles of PDP and therefore exhibits similar computational, cognitive, and biological limitations (Bowers, 2017; Forbus et al. 2017).

## Conclusions

The PDP approach has had a profound effect on the study of cognition. It has provided researchers with a modeling framework which is powerful enough to be applied to almost all domains of cognition and at the same time is sufficiently constrained to not allow turning cognitive

modeling into a computer programming exercise. Importantly, PDP constraints on modeling are not arbitrary or just technical, but they reflect theoretical positions with far-reaching implications. Since its introduction, connectionism has been involved in some of the greatest debates in the cognitive sciences and has led to important theoretical advances, driven by both its proponents and its opponents. Recent progress in deep learning has extended the range of problems which can be addressed by PDP modeling and has opened new promising interdisciplinary lines of research, bringing together results from the study of artificial intelligence, cognitive psychology, and neuroscience.

## Etymology

From the Greek words *para*, meaning “near,” and *phyletic*, meaning “tribe”

## Synonyms

Paraphyly

## Definition

A group of organisms that includes the most recent common ancestor and some – but not all – of its descendants.

Taxonomic groups (treated here only as groups) can be classified according to the kinship between the ► [taxa](#) that compose them, which is the main goal of phylogenetic systematics. In the phylogenetic systematics context, a kinship relationship between taxa is established by the presence of a ► [common ancestor](#) *exclusive* of the group. For example, considering the Mammalia taxon, all species included in Mammalia must be

derived from an exclusive ancestor. In this case, all mammal species and their exclusive ancestor form a ► [monophyletic](#) group. Being so, the members of this group necessarily share exclusive features, called synapomorphies, such as the presence of hair, mammary glands, and others. However, it is common to find in the literature historical groups defined not based on an exclusive ancestor and its descendants but only considering similar features among taxa. These features are often used to categorize and order diversity, as typological Linnaean characteristics, or to demonstrate evolutionary grades, as does the Gradism approach (*see* Brief Historical Perspective section). In the phylogenetic context, these groups that are not recognized based on exclusive shared ancestry are considered unnatural groups and do not represent the evolutionary history of the organisms within.

We can classify unnatural groups into two types: para- and polyphyletic. These two terms were defined by Hennig (1966) and redefined later by other authors. Paraphyletic groups result from the exclusion of small monophyletic groups from a larger monophyletic group. For instance, in Fig. 1, the exclusion of Aves from the larger monophyletic group denotes the paraphyletic group Reptilia. To be recognized as a monophyletic group, Reptilia would have to include Aves (Fig. 1). On the other hand, polyphyletic groups include taxa descendants from two or more different immediate ancestors. An example is the former phylum Radiata, which was mainly created to classify animals with radial symmetry, such as cnidarians, ctenophores, and echinoderms. Since echinoderms have a different immediate ancestor of cnidarians and ctenophores, they do not form neither a monophyletic group nor a paraphyletic one (*see* ► [Monophyletic](#) chapter for more examples). Therefore, the radial symmetry of those taxa arose more than once and is so called homoplasy.

The pursuit to organize the biodiversity based on monophyletic groups is the goal of the phylogenetic systematics (also known as cladistics). However, reference to unnatural groups is commonly found in the literature. Some of the most classic examples are reptiles (explained above),

**Paraphyletic, Fig. 1** Phylogenetic hypothesis of Vertebrata, including Actinopterygii (fish), Amphibia (frog), Mammalia (bat), Testudines (turtle, here considered

as anapsid), Squamata (lizard), Crocodylia (crocodile), and Aves (bird). The paraphyletic group “Reptilia” is highlighted in green

invertebrates (which include all animals, but vertebrates), and gymnosperms (which include all spermatophytes, but angiosperms). Most cladists do not agree with the recognition of non-monophyletic groups since they are not considered real phylogenetic units (i.e., natural groups derived from the process of evolution). However, some authors argue that paraphyletic groups might be recognized as a group of taxa diagnosed by symplesiomorphies (symplesiomorphies are plesiomorphies, i.e., features that maintain their ancestral state, shared with two or more taxa) or by the *absence* of apomorphies (apomorphies are novelty features present in the ancestor and in one or more of its descendants) (Hennig 1966).

### Brief Historical Perspective

The organization and classification of biological entities have been always an activity of interest to humankind. Different criteria of biological classification have been created throughout history, mainly based on the morphological similarity between species, as the Aristotelian system and Linnaean classification. After the emergence of Darwin’s idea of common ancestry, a kinship-

based classification method, called Gradism, was proposed. This method organizes the organisms in levels, i.e., grades, based on the genealogical history of the taxa and their similarities and adaptive capacity (see Wheelis et al. 1992 for details). The Gradism represents one of the first attempts to include the kinship among taxa into a system of organism classification.

The phylogenetic systematics was implemented by Hennig (studies between 1950 and 1970), and consequently, a lot of methods for constructing phylogenetic trees arose. An important contribution of this method was its classification premisses, which state that all taxa must be monophyletic and all information between sister groups (Parallel groups that share a common ancestor) must be expressed. Different from the gradists, Hennig (1966) believed that non-monophyletic groups should not be considered in organism classifications because they do not have an independent history and thus possess neither reality nor individuality. Nevertheless, the author considered that non-monophyletic groups could still be defined based on similarities. For Hennig, a group would be considered para- or polyphyletic depending on the diagnostic feature shared by the taxa in it: paraphyletic are those

groups whose similarities are symplesiomorphies, while polyphyletic groups are those whose similarities are the result of convergence (i.e., homoplasies).

After to Hennig (1966), other authors expanded the definition of para- and polyphyletic groups to include information regarding the phylogenetic relationships among taxa, not relying exclusively on its similarities (e.g., Nelson 1971; Platnick 1977). Therefore, the second half of the twentieth century is filled with discussion on how to designate unnatural groups and the terms to delimit them. In 1981, Bernardi published a work that expanded the definition of these terms and coined the term merophyletic (from the Greek word *mero*, meaning “part”). A merophyletic group corresponds to a larger monophyletic group, from which one or more smaller groups, natural or not, have been removed. According to Bernardi (1981), paraphyletic groups are merophyletic groups that result from the exclusion of one or more smaller monophyletic groups from the larger monophyletic group to which they belong. For example, “Reptilia” is a merophyletic-paraphyletic group, since Aves was excluded from the larger monophyletic group Sauropsida (Fig. 1). Still according to the author, polyphyletic groups are merophyletic groups that result from the exclusion of at least one paraphyletic group from the smallest monophyletic group of which they are part.

Paraphyletic groups, although not being recognized as natural groups, are still being used, especially in didactic perspective, in an attempt to keep traditional names. Therefore, the name of the group should be written between quotes in order to provide an indication that it is not monophyletic.

## Pareidolia

Molly Flessert

Georgia State University, Atlanta, GA, USA

## Introduction

Pareidolia is the phenomenon of recognizing a meaningful pattern, shape, or object from ambiguous forms in visual scenes. We experience pareidolia when an object is perceived even though it is not actually there (Kato and Mugitani 2015; Liu et al. 2014; Mamiya et al. 2016; Proverbio and Galli 2016). When we recognize an animal’s form in the clouds, a pattern of a leaf in a cup of coffee, or the figure of a reaching arm in the shadow of the tree, we are experiencing pareidolia. More notable examples include seeing a man’s face on the moon or Jesus’ portrayal on a piece of toast (Liu et al. 2014). Most studies focus on a specific type of pareidolia – face pareidolia – in which faces or face-like patterns are recognized in the absence of an actual face (Liu et al. 2014; Proverbio and Galli 2016; Ryan et al. 2016; Takahashi and Watanabe 2013; Wardle et al. 2017). Although examples of face pareidolia

emerge spontaneously in the environment, there are also examples of face pareidolia present in various forms of art. For example, Guiseppe Arcimboldo's work depicts human portraits composed of various items such as fruits, vegetables, and flowers.

The experience of face pareidolia is likely caused by our sensitivity to certain categories of importance. Faces are inherently one of the most socially relevant stimuli we encounter (Palermo and Rhodes 2007). They convey socially important information such as an individual's identity, sex, emotional state, etc. On a day-to-day basis we encounter hundreds of faces, resulting in our extreme sensitivity to facial structure, ultimately promoting the rapid detection and identification of different individuals (Crouzet 2010). Their relevance is likely the cause of our ability to so easily recognize face-like patterns even when they are not present (Ryan et al. 2016). From an evolutionary perspective, our threshold for detecting faces could be low in order to avoid any potentially dangerous situations, resulting in an increased number of false positives for seeing faces when they are not actually present (Takahashi and Watanabe 2013). Our susceptibility to such instances of face pareidolia could also be a result of our tendency to anthropomorphize objects (Proverbio and Galli 2016).

Several studies have investigated pareidolia using neurological measures such as event-related potentials (ERPs), functional magnetic resonance imaging (fMRI), or magnetoencephalography (MEG) to see whether activation resulting from illusory faces is associated with activation caused by seeing real faces. For example, the presentation of illusory faces results in activation of the fusiform face area (FFA) – an area of the brain related to face perception (Wardle et al. 2017; Liu et al. 2014). Similarly, Proverbio and Galli (2016) found that images of face pareidolia elicited ERP responses in brain areas involved in face processing, an effect that was stronger in females than in males. Finally, a study using MEG to measure the response to face pareidolia found activation in the ventral fusiform cortex, an area also activated by the perception of real faces. An important aspect to that experiment was that the

presentation of illusory faces resulted in an activation pattern that was not only similar in the brain regions activated but also similar in response times from stimulus onset to activation signal. These results suggest that our perception of face pareidolia is not a post-recognition phenomenon but is rooted in the early stages of visual analysis (Hadjikhani et al. 2009).

Other research has used behavioral measures such as looking time to assess perception of illusory faces. This method builds off research indicating that humans have an innate preference for looking at faces or face-like objects (Farroni et al. 2005). In a study presenting illusory faces to infants ranging in age from 8 to 12 months, researchers found that fixations were most concentrated on the "mouth" areas of images during the simultaneous presentation of sounds (Kato and Mugitani 2015). This behavior is consistent with infants' sound-mouth association or their tendency to look at one's mouth as a source of sound. Infants who were 7- to 9-months old showed a preference for upright Arcimboldo images, but not their inverted counterparts, indicating that they recognize these images as faces (Kobayashi et al. 2012). Beran et al. (2017) presented three and a half to five-year-old children with Arcimboldo images after training them to categorize images of foods and faces. Their results showed that preschool-aged children were successful in categorizing this type of illusory face as a face more often than scattered images, suggesting that, even at this young age, children are susceptible to face pareidolia. And, Takahashi and Watanabe (2013) found that examples of face pareidolia elicited shifts in gaze only when the illusory face pattern was explicitly recognized. Therefore, when illusory faces were perceived, an attentional response similar to that of true faces was triggered.

Several studies, including the fMRI study discussed above (Proverbio and Galli 2016), have investigated whether there are gender differences in perceiving face pareidolia. Gender differences have previously been shown in the perception of other social signals such as reading body language (Krüger et al. 2013) or emotional valence (Kret and De Gelder 2012). For example, two studies investigating gender differences in face pareidolia found

that females recognize Arcimboldo-type illusory faces more readily than males, and that females perceive these illusory faces as more likeable than male perceivers (Pavlova et al. 2016b).

Perception of face pareidolia has also been used as a platform for studying specific aspects of visual processing such as form perception or the underlying mechanism of face processing. For example, humans tend to process stimuli, especially faces, in a global or holistic manner. That is, we view and discriminate objects from each other based on their overall form rather than by their individual parts. For example, Navon (1977) presented stimuli that consisted of smaller letters forming the shape of a larger letter. Adults responded faster to the global form (the larger letter) rather than the local properties (the smaller, individual letters).

Our inherent tendency to process stimuli, especially faces, holistically also makes face pareidolia an ideal platform for studying social disorders in which these perceptual processes are disrupted. For example, individuals with autism spectrum disorder (ASD), in addition to having deficits in discriminating and interpreting social stimuli, typically show a local bias in which they discriminate objects by their individual features instead of global form (Happé and Frith 2006). In general, individuals with ASD are less likely to identify pareidolic faces than typically developing controls (Pavlova et al. 2017; Ryan et al. 2016). Similarly, adults with prosopagnosia (also referred to as “face blindness”) are unable to discriminate faces from each other and have marked deficits in the holistic processing of faces (Avidan et al. 2011; Busigny et al. 2010). However, evidence suggests that despite this impairment in face processing and a bias for local processing, global processing remains intact and allows for the perception of global Navon figures as well as illusory faces (Avidan et al. 2011; Busigny et al. 2010). This is also true for patients with simultanagnosia, who have an extreme local processing bias but are still able to recognize a face-like configuration in Navon and Arcimboldo images (Dalrymple et al. 2007). Individuals with Williams syndrome – who typically exhibit greater attention to faces and social stimuli – were unable to identify faces in pareidolic images

(Pavlova et al. 2016a). Thus, studying whether or not individuals with social disorders such as these perceive illusory faces (in which the local features are not face-like but the global form is face-like) allows for a greater understanding of what perceptual mechanisms underlying face processing are impaired in these populations.

## Comparative Research

Forms of pareidolia in nature may be recognizable to animals. For example, eye-spot patterns are sometimes used by prey species as a method of deterring potential predators. Although eye-spot mimicry has been shown to successfully deter predators, it is unclear whether this is due to the explicit recognition of the eye-like pattern by other animals or more simply due to the conspicuousness of the markings (Kelley and Kelley 2014).

However, comparative research has shown that many species of nonhuman animals experience various visual illusions, some in a similar manner to humans (Fujita et al. 2012; Kelley and Kelley 2014). This research has continued to explore the similarities and differences among human and nonhuman animal perception. Therefore, it is a natural progression of this field to investigate animals’ experience of the pareidolia illusion, especially of face pareidolia given a shared emphasis on the importance of face stimuli across species.

Pareidolia has only recently been studied in nonhuman animals. Faces are an important and socially relevant stimulus to many animal species. For example, multiple species show an inherent tendency to look at faces or the head regions of other individuals (Salva et al. 2011; Sugita 2008). Further, despite typically being local processors for other forms of visual information, the importance of faces is demonstrated by evidence that monkeys process faces holistically (see Parr 2011, for a review). Thus, research has investigated whether the salience of faces is strong enough to elicit this illusion as well as the holistic processing of these illusory faces.

A few recent studies have investigated whether nonhuman primates experience this illusion. In one study with rhesus monkeys and capuchin monkeys,

subjects were first trained to categorize images on a computer as either faces or foods (Beran et al. 2017). After learning this task, monkeys were then presented with Arcimboldo images as well as scattered Arcimboldo portraits, real faces, and object images. Monkeys were just as likely to categorize Arcimboldo images as faces as they were to classify their scattered image counterparts as being faces. These results seem to indicate that the monkeys were unable to perceive these illusory faces, perhaps due to their tendency to process environmental stimuli in a more local manner (i.e., attending to the individual components rather than its whole). If this is the case, then monkeys would fail to recognize the face-like configuration, suggesting instead that face pareidolia is a phenomenon unique to humans.

A second study of nonhuman primates' ability to experience face pareidolia used eye tracking to measure the gaze behavior of rhesus macaque monkeys during the presentation of illusory faces (Taubert et al. 2017). Images of conspecific faces, illusory faces, and content-matched non-face-like objects were presented in a visual paired comparison task in which monkeys were able to freely view images. Because of the monkeys' preference for viewing faces, researchers investigated whether the looking patterns typical of viewing a true face would also be evident when the monkeys viewed images containing illusory faces. The results showed that rhesus monkeys spent more time looking at illusory faces than at objects that did not contain any face-like configuration. In addition to this finding, viewing patterns revealed an increased number of fixations on the "eye" and "mouth" regions of pareidolia images. These viewing patterns are consistent with how nonhuman primates look at images of conspecific faces (Dal Monte et al. 2015), and they suggest that nonhuman primates do possess the ability to perceive illusory faces. Finally, in a similar experiment using rhesus macaque monkeys with bilateral amygdala lesions (an area of the brain involved in face and emotional valence processing), these viewing preferences were no longer apparent, emphasizing the importance of specific brain areas in responding to faces and face-like images (Taubert et al. 2018).

More work in this area will continue to focus on the nature of nonhuman animals' experience of this phenomenon. Specifically, the question remains as to whether the experience of this phenomenon in monkeys is more implicit (like the innate preference to look at face-like patterns) or whether nonhuman primates explicitly recognize the face-like aspects of these images.

## Conclusion

Overall, face pareidolia is a well-established visual phenomenon in humans. The similarity between neural and behavioral responses to real and illusory faces have elucidated the value in studying inanimate objects with illusory facial structure to better understand the neural basis of face perception and its development. Studying this phenomenon in animals will inform our understanding of the mechanisms underscoring face perception in humans as well as illustrate how these mechanisms may have evolved throughout time. Current comparative research has led researchers to draw preliminary, contrasting opinions regarding the perception of illusory faces in nonhuman primates. Therefore, more work is needed to better understand the experience of animals when presented with this illusion. By learning more about illusory perception in other species, we will gain insight into the mechanisms underlying our own perception of real and illusory faces.

Glossary of Terms

Evolution      Change in gene frequencies in populations/species over time via genetic drift, mutation, gene flow, and natural selection.

Fitness (biological)      Extent to which organisms contribute genes to future generations. Often measured as the

|                      |                                                                                                                                                                                                                                          |
